The CPC is important for bi-orientation of each individual chromosome, but it does not ensure that all chromosomes are bi-oriented before anaphase begins. The second mechanism to ensure correct chromosome segregation is the *spindle assembly checkpoint pathway*, a signaling pathway that stops the progression of the cell cycle into anaphase until tension is present at all the kinetochores. Even a single unattached, or inappropriately attached, kinetochore can activate the spindle assembly checkpoint pathway and pause the cell cycle until the error is corrected. An unattached kinetochore drives the assembly of the unstable mitotic checkpoint complex (MCC) as described in detail in Chapter 19. The MCC is an inhibitor of the APC/C and thereby delays entry into anaphase. When all kinetochores are appropriately attached, the MCC disassembles, the APC/C is activated, and the cell proceeds into anaphase.

Anaphase A Moves Chromosomes to Poles by Microtubule Shortening

The onset of anaphase A is one of the most dramatic movements that can be observed in the light microscope. When the spindle assembly checkpoint has been passed, APC/C activation induces proteolysis of the remaining cohesins holding the sister chromatids

together. Suddenly, the two paired sister chromatids separate from each other and are drawn to their respective poles. The movement is sudden because the kinetochore microtubules are under tension, and as soon as the cohesin attachments between the chromatids are removed, the separated chromatids are free to move.

Experiments with isolated metaphase chromosomes have shown that anaphase A movement can be powered by microtubule shortening, using the stored structural strain released after removal of the GTP-bound tubulin subunits at the microtubule tip. This mechanism can be nicely demonstrated in vitro. When metaphase chromosomes are added to purified microtubules, they bind preferentially to the (+) ends of the microtubules. Dilution of the mixture to reduce the concentration of free tubulin dimers results in the movement of the chromosomes toward the (−) ends by microtubule depolymerization at the chromosome-bound (+) ends. In addition, experiments have shown that in *Drosophila*, two members of the microtubule-depolymerizing kinesin-13 protein family (see Figure 18-15) also contribute to chromosome movement in anaphase A. One of these kinesin-13 proteins is localized at the kinetochore and enhances disassembly there (Figure 18-45, **A1**), and the other is localized at the spindle pole, enhancing depolymerization there (Figure 18-45, **A2**). Thus, at least in the fly where it has been studied, anaphase A is powered in part by kinesin-13 proteins specifically localized at the kinetochore and spindle pole to shorten the kinetochore microtubules at both their (+) and (−)

ends, drawing the chromosomes to the poles. In addition, it is hypothesized that the microtubule-severing protein, katanin, may sever microtubules from the γ-TuRC complex at the spindle pole (see Figure 18-7). This makes new (−) ends available for depolymerization, which contributes to microtubule shortening.

FIGURE 18-45 Chromosome movement and spindle pole separation in anaphase. Anaphase A movement is powered by microtubule-shortening kinesin-13 proteins at the kinetochore (**A1**) and at the spindle pole (**A2**). Note that the chromosome arms still point away from the spindle poles due to associated chromokinesin/kinesin-4 members, so the depolymerization force has to be able to overcome the force pulling the arms toward the center of the spindle. Anaphase B also has two components: sliding of antiparallel polar microtubules powered by a kinesin-5 (+) end–directed motor (**B1**), and pulling on astral

microtubules by dynein-dynactin located at the cell cortex (**B2**). Arrows indicate the direction of movement generated by the respective forces.

Anaphase B Separates Poles by the Combined Action of Kinesins and Dynein

Anaphase B causes the spindle to elongate by moving the spindle poles farther apart. A major contributor to this movement are the bipolar kinesin-5 proteins (Figure 18-45, **B1**); kinesin-5 is the same kinesin that is responsible for aster separation in prophase. These motors associate with the overlapping polar microtubules, and since they are (+) end–directed motors, they push the poles apart. While this is happening, the polar microtubules have to grow to accommodate the increased distance between the spindle poles. Another motor — the microtubule (−) end–directed cytoplasmic dynein/dynactin, localized and anchored on the cell cortex — pulls on the astral microtubules, which helps separate the spindle poles (Figure 18-45, **B2**).

The Spindle Is Centered and Oriented by a Dynein/Dynactin-Dependent Pathway

As we discuss shortly, the center of the spindle defines the plane where cell division will occur. Thus it is critical during prometaphase and metaphase that the spindle is placed centrally in the cell to ensure that the two daughter cells will be of equal size. This orientation and placement of the spindle is mediated by dynein/dynactin using two distinct mechanisms (Figure 18-46). Dynein is recruited to the cell cortex by a cortical anchor, allowing it to pull on astral microtubules to move the spindle. The regulation of the placement of the cortical anchor, and hence active dynein/dynactin, is what orients the spindle. First, the chromosomes send out a signal that inhibits the association of the cortical anchor in the vicinity of the chromosomes. This inhibitory signal is the Ran·GTP gradient that we described earlier in this section. The consequence of the Ran·GTP inhibitory signal is that cortical association of dynein/dynactin is restricted to the region of the cell around the spindle poles (Figure 18-46, signal **1**). Second, associated with each spindle pole is a kinase, called *polo-like* kinase, that can phosphorylate substrates in its vicinity, including the dynein/dynactin cortical anchor. Phosphorylation of the cortical anchor renders it unable to recruit dynein/dynactin to the cortex (Figure 18-46, signal **2**). Thus, as a spindle pole gets closer to the cortex, dynein/dynactin dissociates and the spindle moves back toward the center being pulled by dynein/dynactin on the more distal side. This tug of war ultimately moves the spindle into a central position in the cell. This function of dynein/dynactin pulling

on astral microtubules is the same mechanism that contributes to elongation of the spindle during anaphase B (see Figure 18-45).

FIGURE 18-46 Dynein-dynactin centers and orients the spindle (a) During prometaphase and metaphase, the spindle is oriented and centered in the cell by two signals that regulate the location of the active cortical anchor for dynein. First, the chromosomes generate a Ran·GTP gradient (signal **1**) that inhibits association of the cortical anchor with the local cell cortex. Second, polo-like kinase at the spindle poles phosphorylates substrates in the local vicinity that inhibits the association of dynein-dynactin with the cortical anchor (signal **2**). See T. Kiyomitsu and I. M. Cheeseman, 2012, *Nat. Cell Biol.* **14**:311–317.

Cytokinesis Splits the Duplicated Cell in Two

During late anaphase and telophase in animal cells, the cell assembles a microfilament-based *contractile ring* attached to the plasma membrane that will eventually contract and pinch the cell into two, a process known as *cytokinesis* (see Figure 18-38). The contractile ring is a thin band of actin filaments of mixed polarity interspersed with myosin-II bipolar filaments (see Figure 17-35). On receiving a signal, the ring contracts, first to generate a *cleavage furrow* and then to pinch the cell into two.

Two aspects of the contractile ring are essential to its function. First, it has to be appropriately placed in the cell. It is known that this placement is determined by a signal provided by the spindle, so that the ring forms equidistant between the two spindle poles. The signal is provided, at least in part, by the chromosomal passenger complex (CPC) that regulates the attachment of microtubules to kinetochores during prometaphase (see Figure 18-44b). Up to anaphase, the CPC is associated with the inner kinetochores of unseparated chromatids. When anaphase begins, the CPC leaves the kinetochores and associates with the overlapping polar microtubules at the center of the spindle (Figure 18-47a). There the CPC recruits another protein complex, *centralspindlin*, that includes a (+) end–directed kinesin motor protein, which concentrates at the middle of the spindle due to its motor activity (Figure 18-47b). As anaphase B continues, centralspindlin recruits a guanine nucleotide exchange factor for RhoA to the adjacent region of the plasma membrane. Recall from Chapter 17 that Rho proteins are small GTP-

binding proteins that are activated by exchange factors to catalyze the exchange of GDP for GTP (see Figure 17-40). Once activated, the RhoA·GTP activates both a formin protein to drive the nucleation and assembly of actin filaments and myosin-II that together make up the contractile ring (Figure 18-47b, c). In this way, the position of the spindle directly defines the site of contractile ring formation, and hence cytokinesis.

EXPERIMENTAL FIGURE 18-47 The chromosomal passenger complex (CPC) remains at the spindle midzone during anaphase and telophase to direct the assembly of the contractile ring. (a) Micrographs of a cell in late anaphase (*left*) and telophase (*right*), showing

microtubules (red), DNA (blue), Aurora B kinase (green), and kinetochores (magenta). Notice how Aurora B, which is part of the CPC, concentrates in the region where the polar microtubules overlap and where the contractile ring will form. Scale bar $5\ \mu m$. (b) At anaphase, the CPC re-localizes to the region of overlapping microtubules and recruits the centralspindlin complex. This complex contains a kinesin motor that helps to concentrate it near microtubule $(+)$ ends. It recruits and activates a Rho guanine nucleotide exchange factor (RhoA GEF) at the adjacent plasma membrane, which activates RhoA to the GTP-bound form. (c) Pathway showing the interactions that results in the formation of Rho·GTP. This activates a formin to drive assembly of actin filaments, and also activates myosin II (discussed in Chapter 17). Together, the actin and myosin form the contractile ring that pinches the cell in two.

[Part (a) Reprinted with permission from Nature Publishing Group, from S. Ruchaud, M. Carmena, and W. C. Earnshaw, 2007, "Chromosomal Passengers: Conducting Cell Division," *Nat. Rev. Mol. Cell Biol.* **8**:798–812; permission conveyed through Copyright Clearance Center, Inc.]

The second important aspect of the contractile ring is the timing of its contraction. If it were to contract before all of the chromosomes had moved to their respective poles, disastrous genetic consequences would ensue. As we discuss in Chapter 19, a signaling pathway has been discovered in budding yeast called the *spindle position checkpoint*, which pauses the cell cycle to ensure that cytokinesis does not occur until the spindle is appropriately oriented. The mechanism of this coordination in animal cells is still being unraveled.

Plant Cells Reorganize Their Microtubules and Build a New Cell Wall

in Mitosis

Interphase plant cells lack a central MTOC that organizes microtubules into the radiating array typical of animal cells. Instead, numerous MTOCs containing γ-tubulin line the cortex of plant cells and nucleate the assembly of transverse bands of microtubules below the cell wall (Figure 18-48, *left*). These microtubules, which are of mixed polarity, are released from the cortical MTOCs by the action of katanin, a microtubule-severing protein; loss of katanin gives rise to very long microtubules and misshapen cells. The reason for this is that these cortical microtubules, which are cross-linked by plant-specific MAPs, aid in laying down extracellular cellulose microfibrils, the main component of the rigid cell wall (see Figure 20-43).

FIGURE 18-48 Mitosis in a flowering plant cell. Immunofluorescence micrographs (*top*) and corresponding diagrams (*bottom*) showing arrangement of microtubules in interphase and mitotic plant cells. A cortical array of microtubules girdles a cell during interphase. As the cell enters prophase, the microtubules (green), together with actin filaments (red), assemble under the cell cortex into a preprophase band, which marks the future cortical division site. As the cell enters prometaphase and metaphase, a spindle similar to that seen in animal cells forms. However, due to the cell wall, cytokinesis in plant cells is very different from that in animal cells. Microtubules deliver vesicles whose membranes are used to assemble a membrane network called a *phragmoplast*, whose organization is defined by actin filaments linked to the cortical division site. Eventually, the phragmoplast becomes part of the plasma membranes of the two daughter cells. Enzymes secreted from the vesicles then build a cell wall between the two daughter cells. See G. Jürgens, 2005, *Annu. Rev. Plant Biol.* **56**:281–299.

[Micrographs courtesy of Susan Wick.]

Although mitotic events in plant cells are generally similar to those in animal cells, formation of the spindle and cytokinesis has unique features in plants (Figure 18-48). Plant cells bundle their cortical microtubules and actin filaments into a *preprophase band* and reorganize them into a spindle at prophase without the aid of centrosomes. The site of the preprophase band defines the later cortical division site. At metaphase, the mitotic apparatus appears much the same in plant and animal cells. Because plants have cell walls, the division of the cell into two is quite different from animal cells and requires the assembly of a new wall between the daughter cells. Golgi-derived vesicles, which appear at telophase, are transported along microtubules to form the *nascent cell plate*. The cell plate expands and is guided toward the division site by actin filaments to form the **phragmoplast**, a membrane structure that replaces the animal-cell contractile ring. The membranes of the

vesicles forming the phragmoplast become the plasma membranes of the daughter cells. The contents of these vesicles, such as polysaccharide precursors of cellulose and pectin, form the early cell plate, which develops into the new cell wall between the daughter cells. ■

KEY CONCEPTS OF SECTION 18.6

Mitosis

- Mitosis — the accurate separation of duplicated chromosomes — involves a molecular machine comprising dynamic microtubules and microtubule-associated motors.
- The mitotic spindle has three classes of microtubules, all emanating from the spindle poles: kinetochore microtubules, which attach to chromosomes; polar microtubules, which extend from each spindle pole and overlap in the middle of the spindle; and astral microtubules, which extend to the cell cortex (see Figure 18-40).
- In the first stage of mitosis, prophase, the nuclear chromosomes condense and the spindle poles move to either side of the nucleus (see Figure 18-38).
- At prometaphase, the nuclear envelope breaks down and microtubules emanating from the spindle poles capture sister chromatid pairs at their kinetochores. The two kinetochores (one on each chromatid) become attached to opposite spindle poles (bi-oriented), which allows the chromosome to congress to the middle of the spindle.
- The chromosomal passenger complex (CPC) associated with the inner kinetochore keeps microtubule attachments weak by the activity of its kinase component Aurora B, which phosphorylates critical kinetochore proteins. When a chromosome is bi-oriented, tension is generated, and the Aurora B substrates are pulled away from the kinase (see Figure 18-44). Without phosphorylation of kinetochore proteins by Aurora B, the chromosome-kinetochore attachment becomes stable.
- At metaphase, chromosomes are aligned on the metaphase plate. The spindle assembly checkpoint pathway monitors unattached kinetochores and delays anaphase until all chromosomes are attached.
- At anaphase, duplicated chromosomes are separated and moved toward the spindle poles by shortening of the kinetochore microtubules at both the kinetochore and spindle pole (anaphase A). The spindle poles also move apart, pushed by bipolar kinesin-5 moving toward the (+) ends of the polar microtubules (anaphase B).

Spindle separation is also facilitated by cortically located dynein pulling on astral microtubules (see Figure 18-45).

- The spindle is centered and oriented by two signals — a Ran·GTP gradient from the chromosomes and a polo-like kinase gradient from the poles — that negatively regulate the presence or activity of cortical anchors for dynein/dynactin. Active dynein pulls on astral microtubules to center the spindle.
- The position of the contractile ring is directed by the CPC complex that localizes to the middle of the spindle during anaphase. The CPC recruits factors to generate active Rho·GTP at the adjacent plasma membrane to drive the assembly of actin filaments and activate myosin-II. The contractile ring then contracts to pinch the cell in two during cytokinesis (see Figure 18-47).
- In plants, cell division involves the delivery of membranes by microtubules to assemble the phragmoplast, which becomes the plasma membrane of the two daughter cells (see Figure 18-48).

18.7 Intermediate Filaments

The third major cytoskeletal system of animals is the intermediate filaments (IFs). This name reflects their diameter of about 10 nm, which is intermediate between the 7–8-nm diameter of microfilaments and the 25-nm myosin thick filaments of skeletal muscle. IFs extend throughout the cytoplasm as well as lining the inner nuclear envelope of interphase animal cells (Figure 18-49). IFs have several unique properties that distinguish them from microfilaments and microtubules.

1. They are biochemically much more heterogeneous — that is, many different, but evolutionarily related, IF subunits exist — and are often expressed in a tissue-dependent manner.
2. They have great tensile strength, as is demonstrated by hair and nails, which consist primarily of the intermediate filaments of dead cells.
3. They do not have an intrinsic polarity like microfilaments and microtubules, and their constituent subunits do not bind a nucleotide.
4. Because they have no intrinsic polarity, it is not surprising that there are no motors that use them as tracks.
5. They are much more stable than microfilaments and microtubules, because the subunit exchange rate is much slower. Indeed, a standard way to purify intermediate filaments is to subject cells to harsh extraction conditions in a detergent so that all membranes, microfilaments, and microtubules are

solubilized, leaving a residue that is almost exclusively intermediate filaments.

6. Intermediate filaments are not found in all eukaryotes. Fungi and plants lack intermediate filaments, and insects have only one class, represented by two genes.

EXPERIMENTAL FIGURE 18-49 Localization of two types of intermediate filaments in an epithelial cell. Immunofluorescence micrograph of an epithelial cell doubly stained with antibodies to keratin (red) and lamin (blue). A meshwork of lamin intermediate filaments can be seen underlying the nuclear membrane, whereas the keratin filaments extend from the nucleus to the plasma membrane.

These properties make intermediate filaments unique and important structures of metazoans. Their importance is underscored by the identification of hundreds of clinical disorders, some of which are discussed here, associated with mutations in genes encoding IF proteins. To understand their contributions to cell and tissue structure, we first examine the structure of IF proteins and see how they assemble into filaments. Second, we discuss the dynamics of IFs, and third, we describe the different classes of intermediate filaments and the functions they perform.

Intermediate Filaments Are Assembled from Subunit Dimers

In the human genome intermediate filaments are encoded by 70 different genes in at least five classes. The defining feature of IF proteins is the presence of a conserved α-helical rod domain of about 310 residues that has the sequence features of a coiled-coil motif (see Figure 3-7a).

The primary building block of intermediate filaments is a dimer held together through the rod domains, which associate as a coiled coil (Figure 18-50a). Two dimers then associate in an offset fashion to make tetramers, in which the two dimers have opposite orientations (Figure 18-50b). Tetramers are assembled end to end and interlocked into long *protofilaments*. Four protofilaments

associate into a *protofibril*, and four protofibrils associate side to side to generate the 10-nm filament. Thus an intermediate filament has 16 protofilaments in it (Figure 18-50c). Flanking the rod domain of each dimer are nonhelical N- and C-terminal domains of different sizes, characteristic of each IF class (Figure 18-50d). Because the tetramer is symmetric, intermediate filaments have no polarity. This description of the filament is based on its structure rather than its mechanism of assembly. It is not clear how intermediate filaments are assembled in vivo. Unlike microfilaments and microtubules, there are no known intermediate filament nucleating, sequestering, capping, or filament-severing proteins.

FIGURE 18-50 Structure and assembly of intermediate filaments. Drawings of IF protein dimers, tetramers, and mature intermediate filaments. (a) IF proteins form parallel dimers through a highly conserved coiled-coil core domain. The globular heads and tails are quite variable in length (as shown in more detail in panel d) and sequence among IF classes. (b) A tetramer is formed by antiparallel, staggered, side-by-side association of two identical dimers. (c) Tetramers associate end to end and laterally into a protofibril. In a mature filament, consisting of four protofibrils, the globular domains form beaded

clusters on the surface. (d) Comparison of the organization of dimers of vimentin and lamin A. Notice that the lamin protein has a nuclear localization sequence to target it to the nucleus. See H. Hermann et al., 2007, *Nat. Rev. Mol. Cell Biol.* **8**:562.

Intermediate Filaments Are Dynamic

Although intermediate filaments are much more stable than microtubules and microfilaments, IF protein subunits have been shown to be in dynamic equilibrium with the existing IF cytoskeleton. In one experiment, biotin-labeled keratin was injected into fibroblasts; within 2 hours, the labeled protein had been incorporated into the already existing keratin cytoskeleton (Figure 18-51). The results of this experiment and others demonstrate that IF subunits in a soluble pool are able to add themselves to preexisting filaments and that subunits are able to dissociate from intact filaments.

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

EXPERIMENTAL FIGURE 18-51 Keratin intermediate filaments are dynamic, as soluble keratin is incorporated into filaments. Monomeric type I keratin was purified, chemically labeled with biotin, and microinjected into living epithelial cells. The cells were then fixed at different times after injection and stained with an antibody to biotin and with antibodies to keratin. (a) At 20 minutes after injection, the injected biotin-labeled keratin is concentrated in small foci scattered throughout the cytoplasm (*left*) and has not been integrated into the endogenous keratin cytoskeleton (*right*). (b) After 4 hours, the biotin-labeled keratin (*left*) and the keratin filaments (*right*) display identical patterns, indicating that the microinjected protein has become incorporated into the existing cytoskeleton.

Cytoplasmic Intermediate Filament Proteins Are Expressed in a Tissue-Specific Manner

Sequence analysis of IF proteins reveals that they fall into five homology classes, including four localized to the cytoplasm. These IF classes show a strong correspondence to the developmental origin of the cell type in which the IF protein is expressed (Table 18-2). We discuss the fifth class — the nuclear lamins — separately, as they perform functions distinct from the cytoplasmic intermediate filaments.

TABLE 18-2 • The Major Classes of Intermediate Filaments in Mammals

Class	Protein	Distribution	Proposed Function	
I	Acidic keratins	Epithelial cells	Tissue strength and integrity	II	Basic keratins	Epithelial cells		
III	Desmin, GFAP, vimentin	Muscle, glial cells, mesenchymal cells	Sarcomere organization, integrity	IV	Neurofilaments (NFL, NFM, and NFH)	Neurons	Axon organization	V	Lamins	Nucleus	Nuclear structure and organization	

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

The **keratins** that make up IF protein classes I and II are found in epithelia; class III IF proteins are generally found in cells of mesodermal origin; and class IV IF proteins compose the **neurofilaments** found in neurons. The **lamins**, which make up class V, are found lining the nuclei of all animal tissues. Here we briefly summarize the four homology classes found in the cytoplasm and discuss their roles in specific tissues.

Keratins

Keratins provide strength to epithelial cells. The first two IF protein homology classes are the so-called *acidic* and *basic keratins*. There are about 50 genes in the human genome encoding keratins, about evenly split between the acidic and basic classes. Dimers form consisting of one basic keratin chain and one acidic keratin chain.

These dimers then assemble into a filament as described in the previous section.

The keratins are by far the most diverse of the IF protein families. Basic and acidic keratin pairs exhibit different expression patterns both among the various types of epithelia as well as during cell differentiation. The hard keratins make up hair and nails. These keratins are rich in cysteine residues that become oxidized to form disulfide bridges, thereby strengthening the proteins. This property is exploited by hair stylists. If you do not like the shape of your hair, the disulfide bonds in your hair keratin can be reduced, the hair reshaped, and the disulfide bonds re-formed by oxidation — the result is so-called "permanent" hair curling or hair straightening.

The soft keratins, or *cytokeratins*, are found in epithelial cells. The epidermal-cell layers that make up the skin provide a good example of the function of these keratins (Figure 18-52). The lowest layer of cells, the *basal layer*, which is in contact with the basal lamina, proliferates constantly, giving rise to cells called *keratinocytes*. After they leave the basal layer, the keratinocytes differentiate and express abundant cytokeratins. The cytokeratins associate with specialized attachment sites between cells, creating sheets of cells that can withstand abrasion. The keratinocytes eventually die, leaving dead cells with their cytokeratin network but devoid of all cell organelles. This dead cell layer provides an essential barrier to water evaporation, without which we could not survive. The life of a

skin cell, from birth to its loss from the animal as a skin flake, is about one month.

EXPERIMENTAL FIGURE 18-52 Transgenic mice carrying a mutant keratin gene exhibit blistering similar to that in the human disease epidermolysis bullosa simplex. Histological sections through the skin of a normal mouse and a transgenic mouse carrying a mutant K14 keratin gene are shown. In the

normal mouse, the skin consists of a hard outer epidermal layer that covers and is in contact with the soft inner dermal layer. In the skin from the transgenic mouse, the two layers are separated (arrow) due to weakening of the cells at the base of the epidermis.

[Republished with permission from Elsevier, from P. A. Coulombe et al., 1991, "Point Mutations in Human Keratin 14 Genes of Epidermolysis Bullosa Simplex Patients," *Cell* **66**(6):1301–1311; permission conveyed through Copyright Clearance Center, Inc.]

In all epithelia, keratin filaments associate with desmosomes, which link adjacent cells together, and hemidesmosomes, which link cells to the extracellular matrix, thereby giving cells and tissues their strength. These structures are described in more detail in Chapter 20.

In addition to simply providing structural support, there is increasing evidence that keratin filaments provide some organization to organelles and participate in signal transduction pathways. For example, in response to tissue injury, rapid cell growth is induced. It has been shown that in epithelial cells, the growth signal requires an interaction between a cell-growth-signaling molecule and a specific keratin.

Desmin

The class III IF proteins include *vimentin*, found in mesenchymal cells; *GFAP (glial fibrillary acidic protein)*, found in glial cells; and

desmin, found in muscle cells. Desmin provides strength and organization to muscle cells (see cartoons in Table 18-2).

In smooth muscle, desmin filaments link cytoplasmic *dense bodies* to the plasma membrane to ensure that cells resist overstretching. In skeletal muscle, a lattice composed of a band of desmin filaments surrounds the sarcomere. The desmin filaments encircle the Z disk and are cross-linked to the plasma membrane. Longitudinal desmin filaments cross to neighboring Z disks within the myofibril, and connections between desmin filaments around Z disks in adjacent myofibrils serve to cross-link myofibrils into bundles within a muscle cell. The lattice is also attached to the sarcomere through interactions with myosin thick filaments. Because the desmin filaments lie outside the sarcomere, they do not actively participate in generating contractile forces. Rather, desmin plays an essential structural role in maintaining muscle integrity. In transgenic mice lacking desmin, for example, this supporting architecture is disrupted and Z disks are misaligned. The locations and morphology of mitochondria in these mice are also abnormal, suggesting that these intermediate filaments may also contribute to the organization of organelles.

Neurofilaments

Type IV intermediate filaments consist of the three related subunits — NF-L, NF-M, and NF-H (for NF light, medium, and heavy) — that

make up the neurofilaments found in the axons of neurons (see Figure 18-2). The three subunits differ mainly in the size of their C-terminal domains, and all form obligate heterodimers. Experiments with transgenic mice reveal that neurofilaments are necessary to establish the correct diameter of axons, which determines the rate at which nerve impulses are propagated down them.

The structural integrity of the skin is essential in order to withstand abrasion. In humans and mice, the K4 and K14 keratin isoforms form heterodimers that assemble into protofilaments. A mutant K14 with deletions in either the N- or the C-terminal domain can form heterodimers in vitro but does not assemble into protofilaments. The expression of such mutant keratin proteins in cells causes IF networks to break down into aggregates. Transgenic mice that express a mutant K14 protein in the basal stem cells of the epidermis display gross skin abnormalities, primarily blistering of the epidermis, that resemble the human skin disease *epidermolysis bullosa simplex*. Histological examination of the blistered area reveals a high incidence of dead basal cells. The death of these cells appears to be caused by mechanical trauma from rubbing of the skin during movement of the limbs. Without their normal bundles of keratin filaments, the mutant basal cells become fragile and easily damaged, causing the overlying epidermal layers to delaminate and blister (see Figure 18-52). Like the role of desmin filaments in supporting muscle tissue, the general role of keratin filaments appears to maintain the structural integrity of epithelial

tissues by mechanically reinforcing the connections between cells.

Lamins Line the Inner Nuclear Envelope to Provide Organization and Rigidity to the Nucleus

The most widespread IF proteins are the class V proteins, the lamins. Lamins are the progenitors of all IF proteins, from which the cytoplasmic IF proteins arose by gene duplication and mutation. They are the major components of a two-dimensional meshwork called the *nuclear lamina* that lies between the nuclear envelope and the chromatin of the nucleus (Figure 18-53). In humans, three genes encode lamins: one alternatively spliced gene encodes lamins A and C, and two other genes encode lamins B1 and B2. The B-type lamins appear to be the primordial lamin proteins and are expressed in essentially all cells, whereas lamins A and C are developmentally regulated. B lamins are post-translationally prenylated (see Section 10.2), which helps them associate with the inner nuclear envelope membrane. Lamin proteins contain the coiled-coil regions characteristic of intermediate filaments that are needed for dimerization but also have a nuclear localization sequence that targets them to the nucleus as well as a conserved immunoglobulin-like fold (see Figure 18-50d).

FIGURE 18-53 The nuclear lamina is attached to chromatin and through LINC complexes to the cytoskeleton. (a) Diagram of part of a nucleus, showing the association of the lamin-containing nuclear lamina with chromatin and, through the two membranes of the nucleus, with the cytoskeleton. Proteins such as the membrane-associated lamin B receptor and emerin tether the lamin intermediate filaments to the inner nuclear membrane. Lamins are also tethered to the inner nuclear membrane by the prenylation of lamin B (not shown). Diverse linkages, called *LINC complexes*, attach the lamins through the two nuclear membranes to the cytoskeleton. (b) A LINC (*l*inker of *n*ucleoskeleton and *c*ytoskeleton) complex consists of a SUN domain–containing protein that interacts with lamins and extends across the inner nuclear membrane, and a KASH domain–containing protein that interacts with a SUN domain–containing protein in the perinuclear space and crosses the outer nuclear membrane to interact with components of the cytoskeleton. See C. S. Janota et al., 2017, *Cell* **169**:970.

Cells that are subject to mechanical stress have a nuclear lamin meshwork to maintain the integrity of the nucleus. Cells with strong cell walls, such as plant and fungal cells, do not have such a meshwork. The lamin meshwork therefore provides both strength and support to the inner surface of the nuclear membrane. In fact, cells regulate the level of lamin A to match the stiffness of the tissue they are in. Thus neutrophils, for example, which need to move

through thin capillaries and migrate through tight interstitial spaces, have a highly lobulated nucleus as a result of very low levels of lamin A. If they had large, rigid nuclei that were resistant to deformation, they might have trouble squeezing through the small spaces found in the extracellular matrix.

To provide rigidity, the lamin meshwork is associated with chromatin on one side and attached to the cytoskeleton on the other. Some proteins embedded in the inner nuclear membrane, such as the lamin-B receptor and emerin, can bind both chromatin-associated proteins and lamins (see Figure 18-53a). Interestingly, transcriptionally silent regions of the genome are preferentially associated with lamins, and recent evidence suggests that lamins play a role in genome organization and DNA repair. Attachment to the cytoskeleton through both the inner and outer nuclear membranes involves proteins with so-called SUN and KASH domains. The SUN domain proteins are synthesized on the endoplasmic reticulum as transmembrane proteins with their SUN domain in the lumen of the endoplasmic reticulum, and sorting signals in their cytoplasmic domain target them to the outer nuclear membrane, which is continuous with the endoplasmic reticulum. They are then transported as membrane proteins through nuclear pores and, upon reaching the inner nuclear membrane, associate with the nuclear lamina (Figure 18-53b). Nesprins are KASH domain–containing transmembrane proteins of the outer nuclear membrane oriented so that the KASH domain can associate with the SUN domain of another protein in the perinuclear space. The

nesprins, in turn, associate, either directly or through adapters, with intermediate filaments, actin filaments, and microtubules, thereby linking the nucleus to the cytoskeleton (see Figure 18-53b). These attachments are used to move the nucleus to the correct location in a cell as well as transport it, for example, in the long processes of the vertebrate neuroepithelium.

Lamins Are Reversibly Disassembled by Phosphorylation During Mitosis

For the nuclear envelope to be broken down as cells go from prophase to prometaphase during mitosis, the nuclear lamina has to be disassembled. As we discuss in Chapter 19, protein kinases called *mitotic CDKs* drive cells into mitosis, and one of their substrates is the lamins. Phosphorylation of lamins A, B, and C results in disassembly of the intermediate filament lattice into lamin dimers. Due to their C-terminal prenylation, lamin B dimers remain associated with the nuclear membrane. As we saw when we discussed mitosis, depolymerization of the nuclear lamin filaments leads to the disintegration of the nuclear lamina meshwork and contributes to disassembly of the nuclear envelope. During telophase, de-phosphorylation by specific phosphatases promotes lamin reassembly, which is critical to re-formation of a nuclear envelope around the daughter chromosomes. The opposing actions of kinases and phosphatases thus provide a rapid mechanism for

controlling the assembly state of lamin intermediate filaments. Other intermediate filaments undergo similar disassembly and reassembly in other phases of the cell cycle.

There are over 600 mutations located throughout the human gene for lamin A that are known to cause diseases, collectively called *laminopathies*. These diseases include cardiomyopathies, muscular dystrophies, lipodystrophy, and aging-related progeria. Some of these mutations cause Emery-Dreifuss muscular dystrophy (EDMD), most likely because the fragile nuclei cannot stand the stress and strains in the muscle tissue, so these cells are the first to show symptoms. Other forms of EDMD have been traced to mutations in emerin, the lamin-binding membrane protein of the inner nuclear envelope, as well as a nesprin and a SUN protein. Yet other mutations in lamin A cause progeria — accelerated aging, such as Hutchison-Gilford progeria ("prematurely old"). It is still a mystery why different mutations in the same human gene can cause such a wide variety of diseases. ■

KEY CONCEPTS OF SECTION 18.7

Intermediate Filaments

- Intermediate filaments are the only nonpolar fibrous component of the cytoskeleton and are not associated with motor proteins. Intermediate filaments are built from coiled-coil dimers that associate in an antiparallel fashion into tetramers and then into protofilaments, 16 of which make up the filament (see Figure 18-50).
- There are five major classes of intermediate filament proteins, with the nuclear lamins (class V) being the most ancient and ubiquitous in animal cells. The other four classes

show tissue-specific expression (see Table 18-2).

- Keratins (IF classes I and II) are found in animal hair and nails, as well as in cytokeratin filaments that associate with desmosomes in epithelial cells to provide the cells and tissue with strength.
- The class III filaments include vimentin, GFAP, and desmin, which provide structure and order to muscle Z disks and restrain smooth muscle from overextension.
- The neurofilaments make up class IV and are important for the structure of axons.
- The lamins are major components of the nuclear lamina. They contribute to genome organization as well as to the rigidity of the nucleus through linkages to the cytoskeleton involving proteins with SUN and KASH domains (see Figure 18-53).
- Many diseases are associated with defects in intermediate filaments, especially laminopathies, which include a variety of conditions, and mutations in keratin genes, which can cause severe defects in skin (see Figure 18-52).

18.8 Coordination and Cooperation Between Cytoskeletal Elements

So far, we have discussed the three cytoskeletal filament classes — microfilaments, microtubules, and intermediate filaments — as though they mostly function independently of one another. But in reality that is not the case. We saw, for example, that the microtubule-based mitotic spindle determines the site of formation of the microfilament-based contractile ring. We close this chapter with some other examples of linkages, both physical and regulatory, between cytoskeletal elements and their integration into other aspects of cellular organization.

Intermediate Filament–Associated Proteins Contribute to Cellular Organization

There is a group of proteins collectively called *intermediate filament–associated proteins (IFAPs)* that co-purify with intermediate filaments. Among these IFAPs are members of the **plakin** family, which are involved in attaching intermediate filaments to other structures. Some plakins link keratin filaments to desmosomes, which are junctions between epithelial cells that provide stability to a tissue, and hemidesmosomes, which are located at regions of the plasma

membrane where intermediate filaments are linked to the extracellular matrix (these topics are covered in detail in Chapter 20). Other plakins, found bound along intermediate filaments, have binding sites for microfilaments and microtubules. One of these proteins, called *plectin*, can be seen by immunoelectron microscopy to provide connections between microtubules and intermediate filaments (Figure 18-54).

Microfilaments and Microtubules Cooperate to Transport Melanosomes

Studies of mutant mice with light-colored coats have uncovered a pathway in which microtubules and microfilaments cooperate to transport melanosomes. The pigment in mammalian hair is produced in cells called *melanocytes*, cells that are very similar to the fish and frog melanophores discussed earlier (see Figure 18-29). Melanocytes are found in the hair follicle at the base of the hair shaft and contain pigment-laden granules called *melanosomes*. Melanosomes are transported to the dendritic extensions of melanocytes for subsequent exocytosis to the surrounding epithelial cells. Transport to the cell periphery is mediated, just as in frog melanophores, by a kinesin family member. At the periphery, the melanosomes are then handed off to myosin V and delivered for exocytosis. If the myosin V system is defective, the melanosomes are not captured and stay in the melanocyte cell body. Thus microtubules are responsible for the long-range transport of melanosomes, whereas microfilament-based myosin V is responsible for their capture and delivery at the cell cortex. This type of division of labor — long-range transport by microtubules and short-range transport by microfilaments — has been found in many other systems, from transport in filamentous fungi to transport along axons.

Cdc42 Coordinates Microtubules and Microfilaments During Cell Migration

In Chapter 17, we discussed how the polarity of a migrating cell is regulated by small GTPase Cdc42, which results in the formation of an actin-based leading edge at the front of the cell and contraction at the back (see Figure 17-44 and Figure 18-55, step **1**). It turns out that Cdc42 activation at the cell front also leads to polarization of the microtubule cytoskeleton. This phenomenon was originally studied in wound-healing assays (see Figure 17-43), in which it was noticed that when the cells at the edge of a scratch are induced to polarize and move to fill in the empty space, the Golgi complex is moved to the front of the nucleus toward the cell front. Golgi localization at the front of the cell indicates that the centrosome moves to lie in front of the nucleus (recall that Golgi localization is dependent on the location of the MTOC; see Figures 18-1c and 18-28). Recent studies have suggested how this happens. Active Cdc42 at the front of the cell binds the polarity factor Par6, which results in the recruitment of the dynein-dynactin complex (Figure 18-55, step **2**). Cortically localized dynein-dynactin then interacts with microtubules, pulling on them to orient the centrosome and hence the whole radial array of microtubules (Figure 18-55, step **3**). This reorientation of the microtubule system leads to the reorganization of the secretory pathway to deliver secretory products, especially integrins to bind the extracellular matrix, to the front of the cell for

attachment to the substratum for cell migration (Figure 18-55, step 4).

FIGURE 18-55 Independent Cdc42 regulation of microfilaments and microtubules to polarize a migrating cell. Active Cdc42·GTP at the front of the cell leads to Rac and WASp activation, which results in the assembly of a microfilament-based leading edge (step 1) (see Figure 17-44). Independently, Cdc42·GTP also leads to the capture of microtubule (+) ends and the activation of dynein (step 2). Dynein pulls on microtubules to orient the centrosome (step 3) toward the front of the cell. This reorientation reorganizes the secretory pathway for the delivery of adhesion molecules carried in secretory vesicles along microtubules to the front of the cell (step 4). See S. Etienne-Manneville et al., 2005, *J. Cell Biol.* **170**:895–901.

Advancement of Neural Growth Cones Is Coordinated by Microfilaments and Microtubules

The nervous system depends on the integration and transmission of signals by neurons. Neurons have specialized structures, called *dendrites*, that receive signals and a single axon that terminates in one or more synapses on a target cell or cells (see Figure 18-2). It is critical that neurons make the right connections; so how are growing axons guided to their correct destinations? As an axon extends, its terminal growth cone senses signals from the extracellular matrix and from other cells that guide it along the right path. Therefore, how the growth cone receives and interprets cues that direct axon growth is critical to the function of the nervous system. Growth cones are very rich in actin, and they typically have a broad lamellipodium and multiple filopodia. Microtubules are also essential for the guidance of growth cones. Recall that axons have microtubules of uniform polarity along which materials for growth of the axon move by axonal transport (see Figure 18-5e). These microtubules extend into the growth cone and, together with actin, which is necessary for the advancement of the growth cone, are involved in guiding its direction of advancement. Although the mechanisms involved have not been fully elucidated, it has been found that a local growth signal alters local actin dynamics, with the result that microtubules extend into the region of the signal. It has also been found that microtubules in the shaft of the axon have post-translational modifications, such as acetylation, that stabilize them, whereas the more dynamic microtubules in the growth cone often do not (Figure 18-56).

KEY CONCEPTS OF SECTION 18.8

Coordination and Cooperation Between Cytoskeletal Elements

- Intermediate filaments are linked both to specific attachment sites on the plasma membrane (called *desmosomes* and *hemidesmosomes*) and to microfilaments and microtubules (see Figure 18-54).
- In animal cells, microtubules are generally used for the long-range delivery of organelles, whereas microfilaments handle their local delivery.
- The signaling molecule Cdc42 coordinately regulates microfilaments and microtubules during cell migration.
- The advancement of growth cones in neurons requires the interplay of microfilaments and microtubules.

Review the Concepts

1. Microtubules are polar filaments; that is, one end is different from the other. What is the basis for this polarity, how is polarity related to microtubule organization within the cell, and how is polarity related to the intracellular movements powered by microtubule-dependent motors?
2. Microtubules both in vitro and in vivo undergo dynamic instability, and this type of assembly is thought to be intrinsic to the microtubule. What is the current model that accounts for dynamic instability?
3. In cells, microtubule assembly depends on other proteins as well as tubulin concentration and temperature. What types of proteins influence microtubule assembly in vivo, and how does each type affect assembly?
4. Microtubules within a cell appear to be arranged in specific arrays. What cellular structure is responsible for determining the arrangement of microtubules within a cell? How many of these structures are found in a typical cell? Describe how such structures serve to nucleate microtubule assembly.
5. Many drugs that inhibit mitosis bind specifically to tubulin, microtubules, or both. What diseases are such drugs used to treat? Functionally speaking, these drugs can be divided into two groups based on their effect on microtubule assembly. What are the two mechanisms by which such drugs alter microtubule structure?

6. Kinesin-1 was the first member of the kinesin superfamily to be identified and therefore is perhaps the best-characterized superfamily member. What fundamental property of kinesin was used to purify it?
7. Certain cellular components appear to move bidirectionally on microtubules. Describe how this is possible given that microtubule orientation is fixed by the MTOC.
8. The movement of kinesin motor proteins involves both the motor domain and the linker domain. Describe the role of each domain in kinesin movement, direction of movement, or both. Could kinesin-1 with one inactive head efficiently move a vesicle along a microtubule?
9. What features of the dynactin complex enable cytoplasmic dynein to transport cargo toward the microtubule (−) end? What effect could inhibition of dynactin interaction with the +TIP EB1 have on spindle orientation?
10. Cell swimming depends on appendages containing microtubules. What is the underlying structure of these appendages, and how do these structures generate the force required to produce swimming?
11. What effect would dynein inactivation have on kinesin-2-dependent IFT?
12. The mitotic spindle is often described as a microtubule-based cellular machine. The microtubules that constitute the mitotic spindle can be classified into three distinct types. What are the three types of spindle microtubules, and what is the function of each?

13. Mitotic spindle function relies heavily on microtubule motors. For each of the following motor proteins, predict the effect on spindle formation, function, or both of adding a drug that specifically inhibits only that motor: kinesin-5, kinesin-13, and kinesin-4.
14. The poleward movement of kinetochores, and hence chromatids, during anaphase A requires that kinetochores maintain a hold on the shortening microtubules. How does a kinetochore hold onto shortening microtubules?
15. Anaphase B involves the separation of spindle poles. What forces have been proposed to drive this separation? What underlying molecular mechanisms are thought to provide these forces?
16. Cytokinesis, the process of cytoplasmic division, occurs shortly after the separated sister chromatids have neared the opposite spindle poles. How is the plane of cytokinesis determined? What are the respective roles of microtubules and actin filaments in cytokinesis?
17. The best strategy for treating a specific type of human tumor can depend on identifying the type of cell that became cancerous to give rise to the tumor. For some tumors that have colonized a distant location (metastasized), identifying the parental cell type can be difficult. Because the type of IF protein expressed is cell-type-specific, using monoclonal antibodies that react with only one type of IF protein can help in this identification. What IF proteins would you produce monoclonal antibodies against to identify (a) a sarcoma of muscle cell

origin, (b) an epithelial cell carcinoma, and (c) an astrocytoma (glial cell tumor)?

18. Explain why there are no known motors that use intermediate filaments as tracks.
19. Growth cones are highly mobile regions of developing neurons. What prevents the growth cone from moving or collapsing back into the main cell body, as often occurs with lamellipodia?

CHAPTER 19

The Eukaryotic Cell Cycle

Jesse Patterson.

Micrograph on the left shows a human epithelial cell in metaphase. Following DNA replication, cells undergo mitosis to segregate their replicated chromosomes. The cell has aligned its chromosomes (blue) in the center of the mitotic spindle apparatus (green), prior to pulling them to opposite poles of the spindle, which will occur during anaphase. Thereafter, the cytoplasm of the cell is divided to produce two identical daughter cells. The micrograph on the right is the same cell without imaging the spindle apparatus in order to show the location of the centrosomes or spindle poles (red).

19.7 Surveillance Mechanisms in Cell Cycle Regulation
19.8 Meiosis: A Special Type of Cell Division

The central tenet of life and the definition of living matter is inextricably linked to the concept of replication. The pioneering discoveries of Matthias Schleiden and Theodor Schwann, and those of Rudolf Virchow, that living matter was made of cells, and that cells arise only from the division of other cells, dictates that cells proliferate by going through repeated cycles of growth and division of a parent cell into two daughter cells. The daughter cells, in turn, repeat this process, giving rise to more cells. This behavior leads to the general concept of a *cell cycle* that incorporates each of the stages required for cells to replicate themselves: growth in size and nutrient content; duplication of subcellular organelles; DNA replication; chromosome segregation; and finally, separation of the cytoplasmic organelles, contents, and cell membrane between the two progeny. These steps in the cell cycle occur in distinct phases, and the transition from one phase to the next is abrupt and precise. Errors that occur within one phase must be detected and corrected before the cell transits into the next phase. Surveillance mechanisms prevent the transition from one phase of the cell cycle into the next phase until all of the steps of a phase have been completed properly. It is through this process of repeated cell cycles that a fertilized egg — one cell — can eventually give rise to a fully formed animal containing hundreds of millions of cells or more.

Proper control of cell division is vital to all organisms. First, cell division must be balanced with cell growth so that cell size is maintained. If several divisions occur before parent cells have reached the proper size, daughter cells eventually become too small to be viable. If cells grow too large before cell division, the cells function improperly and the number of cells increases too slowly for proper tissue, organ, and animal development during embryogenesis. Second, in developing multicellular organisms, the replication of each cell must be precisely controlled and timed with respect to the replication of other cells in order to faithfully and reproducibly complete the developmental program in every individual in order for complex organs (e.g., the brain, heart, intestine, and kidney) that are made of various cell types to develop properly. Finally, there is a balance between cell replication and cell differentiation, so that cells with high replicative potential are generally much less differentiated into specific cell types, while cells that have highly differentiated into specific lineages usually have quite limited replicative potential. Cells that have the potential to continuously replicate and have not yet differentiated (or have only partially differentiated) but have the ability to differentiate into one or more specific cell types at a later time are called *stem cells*. During embryogenesis in animals, for example, there is a period of rapid cell division after fertilization of the egg, resulting in a small number of cells that have nearly unlimited replicative potential but have not yet undergone any type of differentiation (see Chapter 22).

Their progeny, however, will later differentiate into every type of cell in the body.

In this chapter, we first present an overview of the cell cycle and then describe the various experimental systems that have contributed to our current understanding of it. We discuss the molecular mechanisms responsible for regulating cell cycle progression, particularly the roles of cyclin-dependent kinases (CDKs) as master controllers, along with other protein kinases, phosphatases, phospho-binding modules, and ubiquitin ligases that modulate their activity and function. Next we examine each cell cycle phase in greater detail, with an emphasis on how the events that take place in each phase are governed by protein post-translational modifications, CDK activity, and regulation of downstream targets. We discuss the checkpoint pathways that establish the order of the cell cycle and ensure that each cell cycle phase has been properly and accurately completed prior to transition into the next phase. The chapter concludes with a discussion of meiosis, a special type of cell division that generates haploid germ cells (eggs and sperm), and the molecular mechanisms that distinguish it from mitosis. Throughout the chapter, we emphasize the general principles governing cell cycle progression and use a species-spanning nomenclature when discussing examples of the factors controlling each cell cycle phase.

19.1 Overview of the Cell Cycle

The cell cycle in eukaryotes is a series of processes that occur in a specific sequence every time a cell divides. In cells that are continuously replicating, each process occurs on a schedule, as though the cells were following some type of molecular clock. This clock idea was part of the motivation that eventually led to the discovery of cyclin-CDK complexes as master regulators of the cell division cycle.

The cell cycle is divided into four major phases (Figure 19-1). Cycling (replicating) mammalian somatic cells grow in size and synthesize the RNAs and proteins required for DNA synthesis during the G_1 (first gap) phase. When cells have reached the appropriate size and have synthesized the required proteins, they enter the cell cycle by traversing a point in G_1 known as *START* in yeast and the *restriction point* in mammals. Once this point has been crossed, cells are committed to cell division. The first step toward successful cell division is entry into the S (synthesis) phase, the period in which cells replicate their chromosomes. After progressing through a second gap phase, the G_2 phase, cells begin the complicated process of mitosis, also called the *M (mitotic) phase*.

FIGURE 19-1 The eukaryotic cell cycle. The fate of a single chromosome during different stages of the cell cycle is depicted. Following mitosis (M), daughter cells contain 2*n* chromosomes in diploid organisms and 1*n* chromosomes in haploid organisms. In proliferating cells, G_1 is the period between the "birth" of a cell following mitosis and the initiation of DNA synthesis, which marks the beginning of the S phase. The point in late G_1 when cells become committed to enter S phase is called *START* or the *restriction point*. At the end of the S phase, cells enter G_2 containing twice the number of chromosomes they had as G_1 cells (4*n* in diploid organisms, 2*n* in haploid organisms). The end of G_2 is marked by the onset of mitosis, during which numerous events leading to cell division occur. The G_1, S, and G_2 phases are collectively referred to as

interphase: the period between one mitosis and the next. Most nonproliferating cells in vertebrates leave the cell cycle in G_1, entering the G_0 state. Although chromosomes condense only during mitosis, here they are shown in condensed form throughout the cell cycle to emphasize the number of chromosomes at each stage. The nuclear envelope surrounds the chromosomes during interphase in all cells but breaks down during mitosis in metazoan cells, but not in yeast.

Based on studying cell cycles in budding yeast, Lee Hartwell proposed that cells use specific surveillance mechanisms to ensure that each stage of the cell cycle is properly completed before cells enter the next stage. These surveillance programs establish *checkpoints* at the border between the different cell cycle phases. Cells must pass through the G_1-S checkpoint, for example before they can enter S phase and begin performing DNA synthesis, and they must pass through the G_2-M checkpoint before they can enter mitosis. The progression of cell cycle stages from G_1 to S to G_2 to M is the same for all eukaryotes, though the time it takes to complete one turn of the cycle varies considerably among organisms. Rapidly replicating human cells progress through the full cell cycle in about 24 hours: G_1 takes 9 hours; the S phase, 10 hours; G_2, 4.5 hours; and mitosis, 30 minutes. In contrast, the full cycle takes only 90 minutes in rapidly growing yeast cells. The cell divisions that take place during early embryonic development of the fruit fly *Drosophila melanogaster* are completed in as little as 8 minutes!

G_1 Controls Entry into S Phase

If the purpose of S phase is to duplicate the chromosomal DNA, and the purpose of M phase is to segregate the chromosomes to the daughter cells, what are G_1 and G_2 for? During G_1, a cell must evaluate its status and decide whether it is appropriate to commit to doubling and cell division. This assessment includes an evaluation of the cell's size, nutrient status, substrate attachment, density of neighboring cells, and the presence of extracellular growth factors and other chemicals that stimulate cell division. Growth factors and chemicals that promote cells to transit through the cell cycle and divide are generally referred to as *mitogens*. Specific signaling pathways monitor the state of the cell and its environment, and the outputs of these pathways are integrated to control the decision whether to replicate and divide. The TOR and Hippo signaling pathways, discussed in Chapter 21, monitor a cell's nutrient status, size, attachment status, and the density of surrounding cells. Growth factor signal transduction pathways, the phosphoinositol-3 kinase pathway, and the mitogen-activated protein kinase (MAPK) pathway discussed in Chapter 16, all report on whether mitogens are in the immediate vicinity of the cell.

Once cells commit to replicating their DNA, the decision is irreversible. That is, once cells enter S phase, they must complete the process of duplicating all of their chromosomes regardless of whether growth factors or nutrients are removed from the

extracellular environment. The START or restriction point where cells commit to entering S phase occurs late in G_1; in the case of mammalian cells this point is 2–3 hours prior to S phase onset. The observation that growth factors could be removed after mammalian cells had passed the restriction point (or that nutrients could be removed or mating pheromones that normally arrest yeast cells in G_1 could be added after yeast cells had passed START) and the cells would still progress into S phase led scientists to posit that some mysterious factor was accumulating during G_1, and that once enough of this labile "R-factor" had accumulated, the cells were destined to begin DNA replication. When S phase was nearly completed, this factor would be destroyed, and would have to be re-synthesized during G_1 of the next cell cycle. This cyclic accumulation and degradation of R-factor could explain why cells only synthesized DNA during S phase, and how cells controlled the timing of S phase entry by regulating the levels of R-factor during G_1, based on nutrients, mitogens, cell size, density, and substrate attachment. In mammalian cells, we now know that this cycling R-factor is a protein known as *cyclin D* (likely working in a feedback loop with another protein, cyclin E), and in yeast this factor turned out to be Cln3 working through a feedback loop involving Cln1, Cln2, and a transcriptional repressor called *Whi5*. The term *cyclin* or its abbreviated form, *Cln*, captures the central concept that this labile regulatory factor cycles in abundance as the cells go through the different stages of cell duplication. As we shall see, all of the cyclin proteins play critical roles in controlling the parts of the cell

cycle. Cyclin proteins function at the molecular level by binding to one or more specific protein kinases — the cyclin-dependent kinases (CDKs) mentioned in the introduction — in order to increase the kinase's activity, change the kinase substrate specificity, and localize the kinase to specific parts of the cell.

Once in S phase, complex replication machinery is assembled at specific sites on the chromosomal DNA, at the origins of replication and precise duplication of each chromosome ensues. The centrosome, the main microtubule organizing center in animal cells (see Chapter 18) also duplicates during S phase. Once DNA replication has been completed, cells enter G_2, the second gap phase.

G_2 Phase Readies the Cell for Mitosis and Cell Division

During the G_2 phase, the cell verifies that all of the DNA has been correctly duplicated and is sufficient for producing two cells, errors that were made during DNA copying are corrected, and any breaks in the DNA strands are repaired. In addition, the first signs of chromosome condensation occur, and there is some early reorganization of the cytoskeleton and microtubules as the cell prepares to enter mitosis.

How does the cell know during G_2 when everything is ready for mitosis? As with the transition from G_1 into S phase, another labile cyclin protein accumulates during G_2, which when present in sufficient amounts is able to drive the cells from G_2 into mitosis. In a classic experiment, Tim Hunt added radioactive methionine to fertilized sea urchin eggs and noticed the gradual accumulation of a radiolabeled protein that was precipitously destroyed in mitosis. Work done in a variety of different organisms — budding yeast, frog eggs, sea urchin eggs, sea star, and surf clam embryos — expanded on this observation, and eventually led scientists to clone and characterize this protein, which we now know as cyclin B. The binding of cyclin B to another cyclin-dependent kinase, called *CDK1*, forms an active protein kinase complex that drives the entry of G_2 cells into M phase. Surveillance mechanisms at the G_2-M checkpoint ensure that cells do not progress from G_2 into M phase in the presence of cell stress and damage, such as that caused by radiation, DNA-damaging agents, or drugs that interfere with microtubule polymerization.

Intriguingly, certain organisms, including budding yeast (but not fission yeast), lack a discernable G_2 phase altogether. In other model organisms that have been used to study the cell cycle, such as the frog *Xenopus laevis* and the fruit fly *Drosophila melanogaster*, both the G_1 and G_2 phases appear to be absent during several of the rapid early embryonic cell cycles that occur when the egg first begins to divide, prior to the onset of development. In these cases, the cells

actually divide without growth, making the cells progressively smaller in size. Nonetheless, later cell cycles in these organisms, and most cell cycles in adult organisms in general, require growth during G_1 and the establishment of a G_2 phase between S phase and M phase. Additional accumulation of cell mass including lipid and protein synthesis and mitochondrial division occurs in G_2, while Golgi complex duplication occurs in late G_1, S phase, and G_2.

Mitosis and Cytokinesis Occur During M-Phase

At the completion of S and G_2, the DNA of each chromosome has been duplicated through the process of DNA replication, generating two identical DNA molecules, each of which is also coated with histones and other chromosome-associated proteins (see Figure 8-35). Each of the identical chromosomes is now referred to as a **chromatid** (Figure 19-2). The two sister chromatids are initially held tightly together all along their length by a protein complex called *cohesin*. The chromatid attachment points on mitotic chromosomes are densest at a knobby constricted central region of each chromosome called the **centromere**, which contains many repeated copies of certain DNA sequences. The parts of the chromatid on either side of the centromere are referred to as *arms*. During mitosis, the cohesin links between the two sister chromatids are dissolved, and the sister chromatids are separated from each other

along a proteinaceous spindle made primarily from microtubules; the chromatids ultimately are distributed into each of the two daughter cells.

FIGURE 19-2 Duplication of chromosomes during S phase. Diploid cells contain two of each chromosome, referred to as *chromosome homologs*. At the end of S phase each homologous chromosome has two copies of itself, each copy of which is called a *sister chromatid*. The centromere and chromosome arms are indicated. For simplicity, the cohesin protein that holds the two sister chromatids together is not shown.

The process of separating the two copies of the chromosome is rather elaborate and occurs in a series of six stages that can be recognized when dividing cells are viewed under the microscope, as described in Chapter 18. These stages are summarized in Figure 19-3. To reiterate the main events that occur at each stage: during prophase the chromatin fibers in the nucleus condense into the discrete chromosomes that can be visualized under the light microscope. The cohesin protein that connects the arms of the

duplicated chromosomes to each other from S phase is degraded, leaving the two sister chromatids connected to each other only through cohesin bridges near the centromere. Nucleoli, the sites in the nucleus where ribosome synthesis occurs, disappear. The interphase array of microtubules breaks down, and the centrosomes (which are sometimes now called *mitotic asters* or *spindle poles*) move away from each other as a mitotic spindle begins to form between them. A complex of proteins called the *kinetochore*, which will anchor each chromosome to some of the spindle microtubules, assembles at the centromere of each chromosome.

FIGURE 19-3 The stages of mitosis. The top panels show a diagrammatic representation of key events that occur in each stage of mitosis, the relatively short period of the cell cycle that follows the S and G_2 phases. The bottom panels are micrographs of dividing cells with

the DNA stained blue and the microtubules stained green. Below are listed the major events that occur in each stage.

Next, during prometaphase in higher eukaryotes, the nuclear membrane, the outer part of which was previously contiguous with the endoplasmic reticulum, begins to break down into vesicles and retract back into the endoplasmic reticulum, and the Golgi apparatus breaks down into vesicles. This allows the microtubules emanating from each centrosome to penetrate into the nuclear area and become captured by the kinetochores, becoming kinetochore microtubules. The chromosomes become even more condensed and now appear as the classic thick X-shaped mitotic chromosomes composed of paired sister chromatids (see Figure 1-17). Non-kinetochore microtubules reach across the cell to overlap with those arising from the other centrosome, while a second set of microtubules that face toward the cell membrane and away from the mitotic chromosomes becomes apparent. Following capture of the chromosomes by attachment of their kinetochores to microtubules, the chromosomes begin to move to and fro, with a net movement toward the center of the mitotic spindle.

When the centrosomes have moved to the opposite ends of the cell and the chromosomes have congressed to the middle of the spindle, the cell has entered metaphase. At this point the centromeres at the center of each chromosome have aligned along an imaginary plane midway between the spindle poles called the *metaphase plate*. The

kinetochores of the sister chromatids in each chromosome should now be attached to microtubules coming from opposite poles. Once this correct series of attachments has been confirmed, the cell enters anaphase. During anaphase A, the cohesin glue that held the sister chromatids together at the kinetochores is dissolved; the individual sister chromatids separate from one another and move toward opposite poles of the spindle as the kinetochore microtubules shorten at a rate of about 1 μm/min. During anaphase B, the non-kinetochore microtubules lengthen, causing the cell to elongate as the spindle poles separate further. Once the chromosomes have fully separated to opposite ends of the cell, the cell enters telophase. The chromosomes decondense, the nuclear envelope reforms, nucleoli reappear, any remaining spindle microtubules disassemble, and in animal cells, an actin/myosin–based contractile ring forms just under the plasma membrane in the region of the former spindle midzone. The next step in cell division is cytokinesis, when the cytoplasm becomes divided between the two daughter cells. Historically, cytokinesis was considered a separate process from mitosis, but in this book we follow the current convention to include cytokinesis as the terminal stage of mitosis. Cytokinesis begins in late anaphase or telophase. In animal cells, it involves the formation of a cleavage furrow by narrowing of the contractile ring and severing of any remaining microtubules in the region between where the two daughter cells will separate. The ring slowly closes until the plasma membrane pinches off, forming two discrete cells. The process is somewhat different in yeast, since they must also synthesize a new carbohydrate-based cell wall called

the *septum* at the same time that the actomyosin ring is contracting. In either case — animals or yeast, the end result of mitosis is the same — two daughter cells each containing a nucleus and cytoplasm with a share of the organelles, membranes, and other structures that were present in the mother cell.

All of the stages of mitosis are choreographed by the actions of mitotic protein kinases. As we shall see, cyclin B/CDK1 plays one of the most important roles in controlling the entry into mitosis and in orchestrating many of the molecular events that occur up until the onset of anaphase, when cyclin B is rapidly destroyed. A variety of other protein kinases, including Polo-like kinase, Aurora A and B kinases, and the Nek family of kinases, also play very important roles during the mitotic process. Once again, surveillance mechanisms ensure that each stage of mitosis has been completed properly before moving into the next stage. This is particularly evident at the transition from metaphase to anaphase, where the spindle assembly checkpoint monitors whether each of the chromosomes is properly positioned at the metaphase plate and whether the kinetochores of each sister chromatid are properly attached to microtubules arising from opposite spindle poles.

At the completion of mitosis, the daughter cells can continue cycling or can exit the cell cycle and proceed down a pathway of differentiation. In multicellular organisms, most differentiating cells exit the cell cycle and survive for days, weeks, or in some cases

(e.g., nerve cells and cells of the eye lens) even the lifetime of the organism without dividing again. Such *postmitotic* cells generally exit the cell cycle in G_1 and enter a phase called G_0 (see Figure 19-1). Some G_0 cells can return to the cell cycle and resume replicating; this re-entry is regulated, thereby providing control of cell proliferation.

KEY CONCEPTS OF SECTION 19.1

Overview of the Cell Cycle

- The eukaryotic cell cycle is divided into four phases: G_1 (the period between mitosis and the initiation of nuclear DNA replication), S (the period of nuclear DNA replication), G_2 (the period between the completion of nuclear DNA replication and mitosis), and M (mitosis and cytokinesis).
- Cells commit to a new cell division at a specific point in G_1 known as *START* or the *restriction point*. This commitment involves the integration of multiple signaling pathways that monitor cell size, nutrient status, and the conditions of the extracellular environment.
- Mitogens are growth factors and other molecules that induce cells to divide.
- Labile factors called *cyclins* drive the progression of cells through different stages of the cell cycle by binding to cyclin-dependent protein kinases (CDKs). The resulting cyclin-CDK complexes are present and active only in the cell cycle stage that they promote.
- Surveillance mechanisms, called *checkpoint pathways*, guarantee that each cell cycle step is completed correctly before the next one is initiated.

19.2 Model Organisms and Methods of Studying the Cell Cycle

Unraveling the molecular mechanisms governing cell cycle progression in eukaryotes was remarkably rapid and was fueled by a powerful combination of genetic and biochemical approaches. In this section, we discuss the contributions of several model systems to the discovery of the molecular mechanisms of cell division. Three of the most important systems employed to study the cell cycle are the single-celled yeasts *Saccharomyces cerevisiae* (budding yeast) and *Schizosaccharomyces pombe* (fission yeast) and the oocytes and early embryos of the frog *Xenopus laevis*. Studies using mammalian tissue culture cells led to the characterization of cell cycle control in mammals.

Studies of the cell cycle in many different experimental systems also led to two remarkable discoveries about general control of the cell cycle. First, complex molecular processes such as initiation of DNA replication and entry into mitosis are all regulated and coordinated by a small number of master cell cycle regulatory proteins. Second, these master regulators and the proteins that control them are highly conserved, so that cell cycle studies in fungi, sea urchins, insects, frogs, and other species are directly applicable to all eukaryotic cells, including human cells.

Budding and Fission Yeasts Are Powerful Systems for Genetic Analysis of the Cell Cycle

Budding and fission yeasts have proved to be extraordinarily valuable systems for the study of the cell cycle because of the ease with which they can be genetically manipulated. Both budding and fission yeast belong to the kingdom *Fungi*, but they diverged from each other over 350 million years ago and are therefore only distantly related. In fact, the evolutionary distance between these yeast is similar to the evolutionary distance between each of them and mammals. As a result, studies in both types of yeast reveal valuable insights that directly apply to metazoan animals. Both yeast organisms can exist in the haploid state, carrying only one copy of each chromosome and therefore single copies of each gene. Haploid yeast are an ideal genetic system in which to screen or select for mutants with defects in cell proliferation, because doing the same experiment in diploid organisms would require mutating both copies of a gene. In addition, it is relatively easy to manipulate the expression of individual yeast genes, and yeasts are easy to cultivate and manipulate so that cultures of cells progress through the cell cycle in a synchronous manner.

S. cerevisiae cells are ovoid in shape and divide by budding (Figure 19-4a). The bud, which is the future daughter cell, begins to form concomitant with the initiation of DNA replication and continues to

grow throughout the cell cycle (Figure 19-4b). Cell cycle stage can therefore be inferred from the size of the bud, which makes *S. cerevisiae* a useful system for identifying mutants that are blocked at specific steps in the cell cycle. As with mammalian cells, the budding yeast cell cycle has a long G_1 phase, and the study of the budding yeast cell cycle shaped our understanding of how the G_1–S phase transition is controlled.

FIGURE 19-4 The cell cycle of budding yeast *S. cerevisiae* and fission yeast *S. pombe*. (a) Scanning electron micrograph of *S. cerevisiae* cells at various stages of the cell cycle. The larger the bud that emerges at the end of the G_1 phase, the farther along in the cycle the cell is. Bud scars are also evident at sites where previous daughter cells budded off. (b) Main events in the *S. cerevisiae* cell cycle. The daughter cells must grow to a certain size before they enter START. G_2 is not well defined in budding yeast and is therefore indicated by a dashed arrow. In contrast to higher eukaryotes, the nuclear envelope does not disassemble during mitosis in *S. cerevisiae* and other yeasts, and they undergo a “closed mitosis.”

Complicating matters further, the small *S. cerevisiae* chromosomes do not condense sufficiently to be visible by light microscopy. (c) Scanning electron micrograph of *S. pombe* cells at various stages of the cell cycle. Long cells are about to enter mitosis; short cells have just passed through cytokinesis. (d) Main events in the *S. pombe* cell cycle. This yeast has relatively short G_1 and S phases of the cell cycle and a prominent G_2 stage that is similar to that in metazoan cells. As in *S. cerevisiae*, the nuclear envelope does not break down during mitosis.

Fission yeast cells are rod-shaped, divide in the middle, and grow entirely by elongation at their ends (Figure 19-4c). Consequently, the cell cycle stage of this organism can be inferred from a simple measurement of its length. Cytokinesis occurs by the formation of a septum in the center of the cell, splitting it in two, hence the name *fission yeast* (Figure 19-4d). In contrast to budding yeast and mammalian cells, fission yeast have very short G_1 and S phases of the cell cycle, and instead spend most of the cell cycle in G_2. The molecular mechanisms governing G_2 and entry into mitosis in fission yeast and in metazoan cells are very similar; studies with this organism by Paul Nurse and colleagues revealed the molecular events surrounding the G_2/M phase transition.

Studying yeast mutants that are blocked at specific steps in the cell cycle or that exhibit altered regulation of the cycle has been very useful. Because cell cycle progression is essential for viability, scientists isolated **temperature-sensitive mutants** whose genes encode proteins that are functional at one temperature but become inactive at a different, often higher, temperature (e.g., due to protein

misfolding at the nonpermissive temperature; see Figure 6-6). These mutants, when arrested at a particular cell cycle stage, are easily distinguished from normally dividing cells by microscopic examination. Such cells are called *cdc* (*c*ell *d*ivision *c*ycle) mutants. Identification of the genes mutated in these temperature-sensitive yeast strains provided a comprehensive list of genes critical for virtually all aspects of cell division.

Frog Oocytes and Early Embryos Facilitate Biochemical Characterization of the Cell Cycle Machinery

Although yeast are ideal for large-scale genetic screens, their small size and thick cell wall make them much less suitable for detailed biochemical analysis. To prepare cell extracts for biochemical studies of the cell cycle, the eggs and early embryos of amphibians and marine invertebrates have proven to be particularly suitable. These organisms typically have large eggs, and fertilization is followed by multiple synchronous cell cycles. By isolating large numbers of eggs from females and fertilizing them simultaneously by addition of sperm (or by treating them in ways that mimic fertilization), researchers can obtain extracts from cells at specific points in the cell cycle for analysis of proteins and enzymatic activities.

To understand how *X. laevis* oocytes and eggs can be used for the analysis of cell cycle progression, let's first look at oocyte maturation, which can be recapitulated in vitro. Oocytes undergo a meiotic division (see Figure 19-37 for an overview of meiosis). As oocytes develop in the frog ovary, they replicate their DNA and become arrested in G_2 for 8 months, during which time they grow in size to a diameter of 1 mm, stockpiling all the materials needed for the multiple cell divisions of the early embryo. When stimulated by a male, an adult female's ovarian cells secrete the steroid hormone progesterone, which induces the G_2-arrested oocytes to mature and enter meiosis. As we will see in Section 19.8, meiosis consists of two consecutive chromosome segregation phases known as *meiosis I* and *meiosis II*. Progesterone triggers oocytes to undergo meiosis I and progress to the second meiotic metaphase, where they arrest and await fertilization (Figure 19-5a). At this stage the cells are called *eggs*. When fertilized by sperm, the egg nucleus is released from its metaphase II arrest and completes meiosis. The resulting haploid egg nucleus then fuses with the haploid sperm nucleus, producing a diploid *zygote* nucleus. DNA replication follows, and the first mitotic division of embryogenesis begins (Figure 19-5b). The resulting embryonic cells proceed through 11 more rapid, synchronous cell cycles, generating a hollow sphere of cells called the *blastula*. Cell division then slows, and subsequent divisions are asynchronous, with cells at different positions in the blastula dividing at different times.

FIGURE 19-5 Progesterone stimulates maturation of *Xenopus* oocytes. (a) Step **1**: Progesterone treatment of G_2-arrested *Xenopus* oocytes causes the oocytes to enter meiosis I. The same activity is seen if the oocytes are injected with MPF. Two pairs of synapsed homologous chromosomes (blue) connected to meiotic spindle microtubules (green) are shown schematically to represent cells in metaphase of meiosis I. Step **2**: Segregation of homologous chromosomes and a highly asymmetric cell division expels half the chromosomes into a small cell called the *first polar body*. The oocyte immediately commences meiosis II and arrests in metaphase II to yield an egg. Two chromosomes connected to spindle microtubules are shown schematically to represent egg cells arrested in metaphase of meiosis II. Step **3**: Fertilization by sperm releases eggs from their metaphase arrest, allowing them to proceed through anaphase of meiosis II and undergo a second highly asymmetric cell division that expels one chromatid of each chromosome into a second polar body. The resulting haploid female pronucleus fuses with the haploid sperm pronucleus to produce a diploid zygote. Step **4**: The zygote undergoes DNA replication and the first mitosis. Step **5**: The first mitosis is followed by 11 more synchronous divisions to form a blastula. (b) Micrographs of *Xenopus* eggs transitioning through the cell cycle. (i) G_2-arrested oocytes. (ii) Following progesterone or MPF treatment the oocytes transit from G_2 into meiosis. (iii) Upon fertilization, there is a rise in intracellular Ca^{2+} that triggers cyclin B destruction, leading to completion of meiosis and the first cell division. (iv) The first of the next 11 rapid synchronous cycles of cell division is shown.

The advantage of using *X. laevis* to study factors involved in mitosis is that large numbers of oocytes and eggs can be obtained, and following progesterone treatment and fertilization in the laboratory they will all proceed synchronously through the cell cycle in a manner that can be studied experimentally. Furthermore, the harvested eggs can be crushed by centrifugation in order to prepare reasonably large amounts of an extract that can be induced to undergo mitosis by the addition of sperm nuclei. This makes it possible to carry out biochemical experiments from cells that were all at the same point in the cell cycle. It was in this system that the cyclin-CDK complexes that trigger mitosis and the oscillatory nature of their activity were first discovered. This activity was called *maturation-promoting factor (MPF)* because of its ability to induce entry into meiosis and oocyte maturation when injected into G_2-arrested oocytes and later called *mitosis-promoting factor* when it was shown to induce mitosis in all eukaryotic cells.

The Study of Tissue Culture Cells Uncovers Cell Cycle Regulation in Mammals

Cell cycle regulation in human cells is more complex than in non-mammalian systems. To understand this increased level of complexity, and to understand the cell cycle alterations that are the cause of cancer, it is important to study the cell cycle not only in

model organisms but also in human cells. To study the properties of the human cell cycle, researchers use normal or tumor cells grown in plastic dishes, a method called *tissue culture* or *cell culture* (see Chapter 4). However, note that many of the cell types used to study the human cell cycle have altered cell cycle properties due to genetic alterations that occurred during their culturing or because they were isolated from human tumors. Furthermore, in vitro culture conditions do not resemble those found in the organism and could lead to altered behavior of cells. Although some aspects of mammalian cell division are not recapitulated in cell culture conditions — such as tissue organization and developmental signals governing cell cycle control — cell culture systems nevertheless provide critical insights into the mammalian cell's intrinsic mechanisms governing cell division. Researchers are also working toward establishing culture systems that more closely resemble the cell architecture in tissues. For example, mixtures of different cell types can be grown together to form tissue-like architectures, while embryonic or adult stem cells, or patient-derived tumor cells can be grown in the absence of serum on purified extracellular matrix from tissues, resulting in the formation of self-organizing structures called *organoids* that more closely resemble real organs (see Figure 22-17). More chemically defined polymer lattices are currently being developed that also allow scientists to grow cells in three-dimensional culture mimicking cellular organization within a tissue.

Primary human cells and other mammalian cells have a finite life span when cultured in vitro. Normal human cells, for example, divide 25–50 times, but thereafter proliferation slows and eventually stops. This process is called *replicative senescence*. Some cells can escape this process and become immortalized, allowing researchers to establish cell lines. Although these cell lines harbor genetic alterations that affect some aspects of their proliferation, they are nevertheless a useful tool for studying cell cycle progression in human cells. These cell lines provide an inexhaustible supply of cells that, as we will see next, can be manipulated to progress through the cell cycle in a synchronous manner, allowing for the analysis of protein levels and enzymatic activity at different stages of the cell cycle.

Researchers Use Multiple Tools to Study the Cell Cycle

The experimental analysis of cell cycle properties requires that we be able to determine the cell cycle stage of individual cells. Light microscopy provides some estimate of cell cycle progression. For example, light microscopy allows a researcher to determine whether cultured mammalian cells are in interphase (G_1, S phase, and G_2) or in mitosis. Mammalian tissue culture cells are flat and adhere to their growth surface during interphase, but round up and form spherical structures as they undergo mitosis (Figure 19-6).

Fluorescence microscopy of cellular structures or analysis of specific cell cycle markers — that is, proteins that are present only in certain cell cycle stages — allows for a more accurate determination of cell cycle stage.

Courtesy of Sejal Vyas and Paul Chang, MIT.

FIGURE 19-6 Human cells undergoing mitosis. HeLa Kyoto cells seen under phase contrast microscopy were filmed as they underwent mitosis. The images shown were taken every 20 minutes. Cells are flat during interphase. During mitosis, the cells round up and divide, and acquire a bright and refractile appearance. Subsequently, they flatten out again.

In addition to microscopic tools, cell cycle researchers use flow cytometry to determine the DNA content of a cell population (Figure 19-7; see also Figure 4-1). Cells are treated with a DNA-binding fluorescent dye, and the amount of dye that is incorporated into the DNA of cells is quantitatively assessed using a flow cytometer. Cells are recorded by their DNA content, and the percentages of cells in G_1, S phase, and G_2 or mitosis can be assessed in this manner. Cells in G_1 have half as much DNA as cells in G_2 or mitosis. Cells

undergoing DNA synthesis in S phase have an intermediate amount of DNA.

EXPERIMENTAL FIGURE 19-7 Analysis of DNA content by flow cytometry. Haploid yeast cells were grown in culture and stained with propidium iodide, a fluorescent dye that is incorporated into DNA. The *x* axis shows DNA content, the *y* axis the number of cells. The DNA content analysis shows two predominant populations of cells: cells with unreplicated DNA (1C) and with replicated DNA (2C). The cells between the two peaks represent cells that are in the process of undergoing DNA replication.

To characterize different cell cycle events, it is essential to examine cell populations that progress through the cell cycle in unison. Researchers can generate such populations by *reversibly arresting* cells in a particular cell cycle stage. This cell cycle arrest is usually accomplished by restricting nutrients or growth factors, causing cells to arrest in G_1. In budding yeast, for example, cells treated with a mating pheromone arrest in G_1. When the pheromone is removed from the cells (usually by washing them extensively), the cells exit G_1 and progress through the cell cycle in a synchronous manner. In mammalian cells, removal of growth factors by removing serum from the culture medium (serum starvation) arrests cells in G_0. Re-addition of serum allows cells to re-enter the cell cycle.

Other methods of arresting cells involve blocking a certain cell cycle step with chemicals. Hydroxyurea inhibits DNA replication, leading to arrest in S phase. After removing the drug, cells resume DNA synthesis in unison. Nocodazole disrupts the mitotic spindle and halts the cell cycle in mitosis. Once the drug is washed away, cells resume progression through mitosis in a synchronous manner. In budding and fission yeasts, when temperature-sensitive cdc mutants are incubated at the nonpermissive temperature, they arrest in a particular cell cycle stage because they are defective in a certain key cell cycle protein. Returning cells to the permissive temperature allows them to continue with the cell division cycle in a synchronous fashion.

KEY CONCEPTS OF SECTION 19.2

Model Organisms and Methods of Studying the Cell Cycle

- The ability to isolate mutants of budding and fission yeasts and the use of powerful genetic tools led to the isolation of key genetic factors important for cell cycle regulation.
- Frog eggs and early embryos from synchronously fertilized eggs provide sources of extracts for biochemical studies of cell cycle events, which led to the identification of the oscillatory nature of cyclin-CDK complexes.
- Human tissue culture cells are used to study the properties of the mammalian cell cycle.
- The generation of synchronized cell populations by reversibly arresting cells in a particular cell cycle stage allows researchers to examine the behavior of proteins and cellular processes during the cell cycle.

19.3 Cell Cycle Progression and Control: Feedback Loops and Post-Translational Modification

Progression through the cell cycle is driven, in large part, by the action of cyclin-dependent kinases (CDKs). These protein kinases act as master controllers of the cell cycle by phosphorylating substrates that when properly phosphorylated directly cause the events in each cell cycle stage to take place. In certain phases of the cell cycle, other kinases also play important roles, but the importance of CDKs in each phase of the cell cycle is paramount.

We know from many experimental observations that cells move irreversibly through the cell cycle, and they do so in only one direction (see Figure 19-1): from G_1 to S phase to G_2 to M phase. Cells have never been observed to go backward from G_2 into S phase, nor has anyone ever seen an S phase cell somehow unreplicate its DNA and revert back to a G_1-phase cell. This commitment once cells initiate each phase of the cell cycle means that the activity of these master controllers, the CDKs, must be regulated with extraordinary precision — at just the right time and place and in a manner that is essentially irreversible. Although details of how this is accomplished vary for different cell cycle stages, we will see in subsequent sections that the general molecular basis for CDK regulation is the same no matter which cell cycle stage

we are talking about. It always involves the use of cyclins — the accessory proteins that bind to the CDKs to control their activity — in combination with protein phosphorylation and ubiquitination (see Section 3.4). The control of CDKs can be thought of as occurring in several layers, represented by the concentric circles in Figure 19-8. At the center are the CDKs themselves, along with their activating accessory proteins, the cyclins. In the second layer are the direct regulators of the cyclin-CDK complexes, which includes protein kinases and phosphatases that activate or inhibit the CDKs, together with CDK inhibitor proteins that bind directly to the CDKs to block their activity, transcription factors that increase the rate of cyclin synthesis to create active cyclin-CDK complexes at specific points in the cell cycle and protein kinases and ubiquitin ligases that work together to promote the destruction of the cyclins once cells have completed a specific part of the cell cycle. In the outer layer are the indirect regulators of the cyclin-CDK complexes that function by regulating the direct regulators (Figure 19-8). Like the second layer of control, this third layer of indirect regulators is also composed of protein kinases and ubiquitin ligases, which work together with phosphoserine/threonine-binding domains and proline isomerases to control the levels, activity, and subcellular location of the direct regulators of cyclin-CDK activity. This multilayered network of control allows a cell to evaluate the massive amount of information about the state a cell finds itself in. A cell then integrates the information into all-or-none step-function-like decisions that control the onset of DNA replication or the initiation of mitosis, for example. Note that this information is reflected by gradual linear

changes in the activity of various signaling pathways. The combination of direct and indirect control afforded by this multilayered regulatory network allows a very small set of basic biochemical reactions — protein phosphorylation and de-phosphorylation, molecular recognition, and ubiquitin-mediated protein destruction — to build feed-forward and feedback loops that provide fine control of whether a cell cycle transition takes place. In addition, the outermost circle of indirect regulation provides the molecular basis for cell cycle checkpoint control, as explored in Section 19.7.

FIGURE 19-8 A multilayered network controls the activity of cyclin-dependent kinases. Concentric circles indicate the CDKs and their activating cyclins in the center, surrounded by their direct regulators, and then their indirect regulators. As shown in the key, the shapes

represent kinases, phosphatases, proline isomerases, phosphoserine/threonine-binding proteins and domains, cyclin kinase inhibitors, and ubiquitin ligases. Black lines generally denote activation of the indicated protein's target, while red lines denote inhibition. Feedback loops involving phosphorylation of the regulators by the cyclin-CDKs are not shown to maintain clarity. Note that there is substantial cross talk among the molecules and that the number of molecules and interactions are more complex than is shown here.

In the following sections, we describe the current model of eukaryotic cell cycle regulation, which is summarized in Figure 19-9. A key discovery in cell cycle studies was that cyclin-dependent kinases govern progression through the cell cycle. Three key features of these kinases are important to keep in mind throughout this chapter.

- Cyclin-dependent kinases (CDKs) are active only when bound to a regulatory cyclin subunit.
- Different types of cyclin-CDK complexes initiate different events. **G_1 cyclin-CDKs** and **G_1/S phase cyclin-CDKs** promote entry into the cell cycle, **S phase cyclin-CDKs** trigger S phase, and **mitotic cyclin-CDKs** initiate the events of mitosis (Figure 19-9).
- Multiple biochemical mechanisms ensure that the CDKs are active only in the stages of the cell cycle they trigger. These molecular mechanisms are organized into feedback loops that amplify the process of CDK activation and inhibition.

FIGURE 19-9 An overview of how CDKs regulate cell cycle progression. Cells harbor different types of CDKs that initiate different events of the cell cycle. Importantly, the CDKs are active only in the stages of the cell cycle that they trigger. G_1/S phase CDKs are active at the G_1–S phase transition to trigger entry into the cell cycle. S phase CDKs are active during S phase and trigger DNA replication. Mitotic CDKs are active during mitosis and trigger mitosis. The anaphase-promoting complex or cyclosome (APC/C) ubiquitin-protein ligase catalyzes two key cell cycle transitions by ubiquitinylating proteins, hence targeting them for degradation. APC/C initiates both anaphase and exit from mitosis. The names of the different CDKs and their associated cyclin subunits for yeast and humans are listed.

In this section, we discuss the properties of CDKs and investigate the structural basis of their activation and regulation. We then describe how cyclins activate CDKs and investigate the general regulatory mechanisms that restrict different cyclins to the appropriate cell cycle stage. We will see that protein degradation plays an essential part in this process, as do post-translational modifications to CDKs and inhibitory proteins that directly bind to cyclin-CDK complexes.

Cyclin-Dependent Kinases Are Small Protein Kinases That Require a Regulatory Cyclin Subunit for Their Activity

Cyclin-dependent kinases constitute a family of small (30–40 kDa) serine/threonine kinases that contain little more than the kinase domain. By themselves, monomeric CDKs are not active, and in general, their protein levels in the cell remain relatively constant throughout the cell cycle. The activity of these CDKs and the amounts of the substrates that they phosphorylate, however, change dramatically in the different cell cycle stages. These changes occur because the CDKs require the binding of an activating subunit — a cyclin — to become active protein kinases.

In budding and fission yeasts, a single CDK controls progression through the cell cycle. Its activity, and the specific substrates that it

phosphorylates, is specified by which of several cell-cycle-stage-specific cyclin subunits it is bound to. Mammalian cells, in contrast, contain as many as 20 different CDKs, with 4 of them, CDK1, CDK2, CDK4, and CDK6, having clear roles in regulating cell cycle progression. Each CDK binds to one or more cyclin subunits that control CDK activity and substrate preference. The different mammalian CDKs, together with their specific cyclins, promote different cell cycle transitions. Mammalian CDK4 and CDK6, for example are G_1 CDKs that promote entry into the cell cycle, CDK2 functions as a G_1/S phase and S phase CDK, and CDK1 is the mitotic CDK. For historical reasons, the names of various cyclin-dependent kinases from yeasts and vertebrates differ. Whenever possible, we will use the general terms G_1, G_1/S phase, S phase, and mitotic CDKs to describe CDKs instead of the species-specific terminology. The bottom of Figure 19-9 lists the names of the various mammalian and budding yeast cyclin-CDKs and indicates when in the cell cycle they are active.

Cyclins Determine the Activity of CDKs

Cyclins are so named because their concentrations change during the cell cycle. They form a family of proteins that is defined by three features.

- Cyclins bind to and activate CDKs. The activity and substrate specificity of any given CDK is primarily defined by the

particular bound cyclin.

- Cyclins are present only during the cell cycle stage that they trigger and are absent from other cell cycle stages.
- In addition to triggering a particular cell cycle stage, cyclins also set in motion a series of events in preparation for the next cell cycle stage. In this way, they propel the cell cycle forward (Figure 19-10a).

FIGURE 19-10 CDK activity during the cell cycle is regulated by binding to different cyclins. (a) The activity of different CDKs varies as cells transit through the stages of the cell cycle, as indicated in Figure 19-9. (b) The protein levels of different cyclin subunits that form the cell-cycle-stage-specific CDK complexes rise and fall in a cell-cycle-stage-specific manner. (c) The activity of the different cyclin-CDK complexes that are formed by the different cyclin-CDK complexes varies in a manner that is very similar, but not exactly identical to the accumulation of the cyclins. The difference between cyclin abundance in panel (b) and kinase activity shown in panel (c) indicates that there must be additional levels of regulation of cyclin-CDK activity, such as phosphorylation and de-phosphorylation in addition to cyclin binding.

Similar to the nomenclature used for CDKs, cyclins are divided into four classes defined by their presence and activity during specific phases of the cell cycle: G_1 cyclins, G_1/S phase cyclins, S phase cyclins, and mitotic cyclins (see Figure 19-9, *bottom*). Some cyclins can bind to and activate more than one CDK, while others can only bind to a single CDK. In mammalian cells, for example, cyclin A can form an activating complex with both CDK2 in S phase, and with

CDK1 at the very beginning of mitosis. In contrast, cyclin B, the main mitotic cyclin, can only form a complex with CDK1.

The G_1 cyclins are the linchpin in coordinating the cell cycle with extracellular events. Their activity is subject to regulation by signal transduction pathways that sense the presence of growth factors or cell proliferation inhibitory signals. In metazoans, G_1 cyclins are known as *cyclin Ds*, and they bind to CDK4 and CDK6. Unlike other cyclins, G_1 cyclins levels do not show strong, stage-dependent fluctuations. Instead, in response to macromolecule biosynthesis and extracellular signals, their levels gradually increase in G_1, drop a bit during S and G_2 phase, and rise again during late M phase (Figure 19-10b).

The G_1/S cyclins accumulate during late G_1, reach peak levels when cells enter S phase, and decline during S phase (Figure 19-10b). They are known as *cyclin E* in metazoans and bind to CDK2. The main function of cyclin E–CDK2 complexes, together with cyclin D–CDK4/6, is to trigger the G_1–S phase transition. This transition, which we defined in Section 19.1 as START in yeast and the restriction point in mammalian cells, is defined as the point at which cells are irreversibly committed to cell division and can no longer return to the G_1 state. In molecular terms, this means that cells initiate DNA replication as well as duplicating their centrosomes, which is the first step in the formation of the mitotic spindle that will be used during mitosis.

S phase cyclins are synthesized concomitantly with G_1 cyclins, but their levels remain high throughout S phase and do not decline until early mitosis. Two types of S phase cyclins trigger S phase in metazoans: cyclin E, which can also promote entry into the cell cycle and is therefore also a G_1/S cyclin, and cyclin A. Both cyclins bind CDK2 and are directly responsible for DNA synthesis. As we will see in Section 19.4, these protein kinases phosphorylate proteins that activate DNA helicases and load polymerases onto DNA.

Mitotic cyclins bind to CDK1 to promote entry into and progression through mitosis. The metazoan mitotic cyclins are cyclins A and cyclins B (note that cyclin A can also trigger S phase when bound to CDK2). Mitotic cyclin-CDK complexes are synthesized during S phase and G_2, but as we will see shortly, their activities are held in check until DNA synthesis is completed. In Section 19.5, we will see that once activated, mitotic CDKs promote entry into mitosis by phosphorylating and activating hundreds of proteins to promote chromosome condensation, nuclear envelope breakdown, mitotic spindle formation, and other aspects of mitosis. Their inactivation during anaphase prompts cells to exit mitosis, which involves the disassembly of the mitotic spindle, chromosome decondensation, the re-formation of the nuclear envelope, and eventually cytokinesis.

Mitotic cyclins were the first set of cyclins to be discovered, and it was their characterization that led to the discovery of the oscillatory nature of the activities that govern all of cell cycle progression. An impressive series of genetic and biochemical experiments in fission yeast by Paul Nurse and colleagues in the 1980s, building on related work from Lee Hartwell in budding yeast, had established that mitotic entry required the activity of a specific protein kinase, called *Cdc2* in fission yeast and *Cdc28* in budding yeast, and characterized some aspects of how this kinase was regulated. Independently, biochemical experiments in sea star embryos and eggs from frogs, surf clams, and sea urchins in the 1970s and 1980s had suggested that the maturation-promoting factor/mitosis-promoting factor (MPF) in those organisms, which we described in Section 19.2, might involve this same protein kinase. In a remarkable experiment in 1982, while studying protein synthesis in sea urchin eggs after fertilization, Tim Hunt unexpectedly observed a protein that showed cycles of synthesis followed by rapid destruction. The timing of this protein's destruction occurred just before the cells physically split into two, suggesting that its synthesis correlated with mitotic entry, and its destruction correlated with completion of mitosis (Figure 19-11). A similar pattern of cyclic protein synthesis and destruction was seen for two related proteins in clam eggs. These findings hinted that these proteins might be the mysterious labile factor(s) mentioned in Section 19.1 that control the switch from G_2 to mitosis. Cloning of their cDNAs further contributed to the identification of the proteins as sea urchin cyclin B and clam cyclin A. These cyclin

proteins were not the critical protein kinases that drove budding yeast, fission yeast, or vertebrate eggs and embryos into mitosis themselves, but cyclin immunoprecipitates (see Section 3.5) from the eggs had strong protein kinase activity. Furthermore, the addition of the sea urchin cyclin cDNA to RNase-treated frog egg extracts could drive the extracts through several rounds of cell cycles, indicating that these cyclin proteins were associating with and activating the protein kinases that were responsible for cell division.

EXPERIMENTAL FIGURE 19-11 How cyclins were discovered. The discovery of cyclins was based on the observation that the levels of a newly translated protein, labeled A in the autoradiogram, peaked in abundance and then rapidly declined each time before a sea urchin cell divided. In this experiment, the eggs were fertilized and incubated with radioactive methionine. Samples were then analyzed at 10-minute intervals using SDS-PAGE and autoradiography, and the eggs were also examined microscopically for cleavage. Compare the levels of one protein on the gel, labeled B, which progressively accumulates, with the levels of protein A that seems to rise and fall just before the cells undergo cleavage. The band intensities and cleavage fraction, as a function of time, are quantified in the graph. Protein A is the mitotic cyclin.

Ultimately, the composition of MPF from frog eggs was resolved by biochemical purification of MPF followed by protein analysis using SDS-PAGE. This revealed two bands, one at 32 kDa, similar in size to that of the yeast Cdc2 kinase, and a second band at 45 kDa that corresponded to cyclin B, indicating that frog egg MPF was, in fact, a complex between cyclin B and the mitotic CDK1 kinase. At around the same time, genetics experiments in fission yeast revealed a critical regulator for Cdc2, the yeast CDK, to be another cell division cycle gene, Cdc13. Cloning and sequencing of Cdc13 revealed that it was the fission yeast homolog of cyclin B. The levels of Cdc13 were shown to vary during the yeast cell cycle, just as cyclin B did during the sea urchin cell cycle. In addition, just as cyclin B was required for CDK1 kinase activity, Cdc13 was required for Cdc2 protein kinase

activity, and this complex, formed by a mitotic cyclin and a cyclin-dependent kinase (Cdc13 and Cdc2, respectively) was required for fission yeast to progress from G_2 into M phase. This combination of genetics and biochemical experiments performed in so many of the different organisms discussed in Section 19.2 ultimately revealed a universal mechanism that controls mitotic entry for all eukaryotic life forms: the formation of a complex between an unstable cyclin molecule and a small cyclin-dependent protein kinase whose activity is strictly dependent on the presence of the cyclin subunit. Subsequent studies showed that G_1/S phase cyclins had similar properties. Their expression is sufficient to promote entry of resting cells from G_1 into S phase, and subsequent movement through S phase.

How exactly does cyclin-binding convert CDKs from an inactive to an active state? The three-dimensional structure of CDKs and cyclin-CDK complexes, solved for cyclin B/CDK1 and cyclin A/CDK2 by x-ray crystallography, provides an answer (Figure 19-12). As discussed in Chapter 3, cyclin-dependent kinases, like all protein kinases, are bilobed structures, with an active site cleft where both ATP and substrates bind. In the absence of cyclin binding, however, several of the catalytic residues in the CDK are not in the proper position to bind ATP and catalyze the transfer of a phosphate group from ATP to the substrate proteins. In addition, the activation loop of the monomeric CDK blocks substrates from accessing the active site cleft. Cyclins are composed of two domains, each containing five α

helices. The overall structure is called a *cyclin fold*, and the first domain corresponds to the *cyclin box* region that is required for CDK binding and activation. In the case of CDK1 and CDK2, binding of the cyclin box causes an α helix in the CDK to move, reorganizing the amino acids in the ATP-binding pocket of the CDK into a more productive conformation for catalysis. In addition, cyclin binding structures and repositions the activation loop, as we discuss shortly. Besides stimulating CDK activity, the cyclin subunit can also interact directly with substrate proteins of the kinase, thereby contributing to the substrate specificity of the cyclin-CDK complex.

FIGURE 19-12 Structural models of human CDK2. (a) Free, inactive CDK2 not bound to its cyclin subunit, cyclin A. In free CDK2, the A-loop blocks access of protein substrates to the γ phosphate of the bound ATP, shown as a stick model. The conformations of the A-loop and the region highlighted in yellow (α1 helix) are altered when CDK is bound to cyclin A. (b) Nonphosphorylated, low-activity cyclin A-CDK2 complex. Conformational changes induced by binding of a domain of cyclin A (blue) cause the A-loop to pull away from the active site of CDK2 so that substrate proteins can bind. The α1 helix in CDK2, which interacts extensively with cyclin A, moves several angstroms into the catalytic cleft, repositioning key catalytic side chains required for the phosphotransfer reaction. The black ball marks the position of the threonine (Thr-160) whose phosphorylation by CAK activates CDKs. The red balls mark

the positions of phosphorylated Thr-14 and Tyr-15, which inhibit CDK activity. (c) Phosphorylated, high-activity cyclin A-CDK2 complex. The conformational changes induced by phosphorylation of the activating threonine (black ball) alter the shape of the substrate-binding surface, greatly increasing the affinity for protein substrates. Removal of the phosphate groups from Thr-14 and Tyr-15 enhances ATP binding and catalytic activity. See P. D. Jeffrey et al., 1995, *Nature* **376**:313–320.

CDKs Are Regulated by Activating and Inhibitory Phosphorylation

As we will discuss in detail below, in addition to cyclin-binding, a variety of other mechanisms ensure that CDKs are only active at the right stage of the cell cycle. Table 19-1 lists many of these additional key regulators of CDKs.

TABLE 19-1 • Regulators of Cyclin-CDK Activity

Type of Regulator	Function
Kinases and Phosphatases	
CAK kinase	Activates CDKs in all organisms
Wee1 kinase	Inhibits CDKs in all organisms
Cdc25 phosphatase	Activates CDKs in fission yeast

Cdc14 phosphatase	Activates Cdh1 to degrade mitotic cyclins in budding yeast
Cdc25A phosphatase	Activates vertebrate S phase CDKs
Cdc25B and C phosphatases	Activate vertebrate mitotic CDKs
Inhibitory Proteins	
Sic1	Binds and inhibits S phase CDKs in budding yeast
CKIs $p27^{KIP1}$, $p57^{KIP2}$, and $p21^{CIP}$	Bind and inhibit CDKs in animal cells
INK4	Binds and inhibits G_1 CDKs in animal cells
Rb	Binds E2Fs, preventing transcription of multiple cell cycle genes in animal cells
Ubiquitin-Protein Ligases	
SCF	Degradation of phosphorylated Sic1 or $p27^{KIP1}$ to activate S phase CDKs
APC/C^{Cdc20}	Degradation of securin, initiating anaphase. Induces degradation of B-type cyclins
APC/C^{Cdh1}	Degradation of B-type cyclins in G_1 and geminin in metazoans to allow loading of replicative helicases on DNA replication origins
Phosphoserine/Threonine-Binding Proteins and Modular Domains	
WD40 domains, leucine-rich	Recognize phosphorylated substrates and target them for degradation by SCF ligases

repeats	
Cks subunits	Target cyclin-CDKs for processive substrate phosphorylation
14-3-3 proteins	Bind and inactivate regulators of cyclin-CDKs to establish cell cycle checkpoints. Also regulates cytokinesis.
Pin1	Isomerizes phosphorylated substrates of CDKs to control mitotic entry and exit
FHA and BRCT domains	Form phospho-dependent molecular assemblies necessary for cell cycle surveillance mechanisms in all stages of the cell cycle, and regulates cytokinesis.
Polo-box domains	Target Polo kinases to sites of CDK phosphorylation to drive mitotic entry and progression

If cyclin-binding was the only thing required for CDKs to become fully active, then one would expect the activity of each CDK to perfectly parallel the accumulation of its cyclin partner. However, that is not what is observed for most cyclin-CDK pairs. Figure 19-13a shows the accumulation of cyclin B, and the activity of MPF (the cyclin B-CDK1 complex in *Xenopus* oocytes). The abrupt rise of MPF activity observed upon entering mitosis, despite the slow progressive rise in the amount of cyclin B present, indicates that additional types of regulation must be present besides cyclin binding. Indeed, at least two additional mechanisms are involved in controlling the activity of CDKs: activating and inhibitory phosphorylations on the CDK subunit, and the action of inhibitor proteins, called *CKIs (c*yclin *k*inase *i*nhibitors) that bind to CDK to

block its activity. These three regulatory events — cyclin binding, phosphorylation, and CKIs — together with cyclin synthesis and destruction, ensure that CDKs are active only at the appropriate time and cell cycle stage.

FIGURE 19-13 Phosphorylation of the CDK subunit restrains mitotic CDK activity during S phase and G_2. (a) Mitotic cyclin B is synthesized during S phase and G_2 and binds to CDK1, but the complex does not become active until aound the time of mitotic entry. (b) The cyclin-CDK complex is not active because threonine 14 and tyrosine 15 of the CDK1 subunit are phosphorylated by the protein kinase Wee1, which inhibits the accumulation of the active form. Once DNA replication has been completed, the protein phosphatase Cdc25 is

activated and de-phosphorylates CDK1, promoting its activity. A positive feedback loop, indicated by the black curved arrows and discussed in Section 19.5, controls the activation of Cdc25 and inhibits Wee1 in animal cells.

Nonphosphorylated CDK bound to one of its cyclin partners has minimal but detectable protein kinase activity in vitro, although it may be essentially inactive in vivo. This is because the activation loop, though partially structured by cyclin binding, still largely blocks the catalytic cleft (see Figure 19-12b). Phosphorylation of a critical threonine residue in the activation loop, Thr-160, is needed to pull the activation loop out of the way by tethering it to several basic residues in the CDK, allowing substrates to access the active site of the CDK and increasing the activity of the phosphorylated cyclin-CDK complex by over a hundredfold compared to the nonphosphorylated complex (see Figure 19-12c). This threonine phosphorylation is mediated by **CDK-activating kinase (CAK)**. Curiously, CAK activity is constant throughout the cell cycle and the activating phosphorylation of the CDK occurs either before or as soon as a cyclin-CDK complex is formed, so it is clear that CAK phosphorylation of the CDK is not a rate-limiting step in CDK activation. Why, then, does cyclin B/CDK1 (MPF) activity rise so rapidly when cells go from G_2 into M phase (Figure 19-13), if the threonine-phosphorylated cyclin B–bound kinase is already present? This behavior arises because the CDK also contains inhibitory phosphorylations.

The two inhibitory phosphorylations on CDK play a critical role in controlling CDK activity. A highly conserved tyrosine (Y15 in human CDKs) and an adjacent threonine (T14 in humans) are subject to regulated phosphorylation (see Figures 19-12b and 19-13b). Importantly, both of these residues are situated in the G-loop of the CDK, containing the consensus sequence GXGXXGXV, that drapes over the phosphate groups in ATP (see Figures 19-13 and 3-38). In the case of CDKs, the G-loop sequence is $GEGT_{14}Y_{15}GVV$. Phosphorylation of T14 and Y15 in this G-loop introduces significant negative charge that electrostatically interferes with the binding and positioning of ATP in the catalytic pocket. Changes in the phosphorylation of these sites are essential for the regulation of mitotic CDKs and have also been implicated in the control of G_1/S and S phase CDKs. As we will see in Section 19.5, a highly conserved kinase called *Wee1* brings about these inhibitory phosphorylations, and a family of highly conserved phosphatases called *Cdc25*, mediates their de-phosphorylation (Figure 19-13b).

CDK Inhibitors Provide Additional Control of Cyclin-CDK Activity

In addition to cyclin binding and reversible phosphorylations on the CDK itself, there is one more level of control of cyclin-CDK activity. A family of proteins known as *CDK inhibitors* or *CKIs* bind directly to CDKs and cyclin-CDK complexes to inhibit their activity. Different

classes of CKIs act in G_1, at the G_1–S boundary, or in S and G_2 phases of the cell cycle to prevent premature activation of G_1, S phase, and M phase CDKs.

An important class of CKIs acting in G_1 are members of the *INK4s* (*in*hibitors of *k*inase *4*) family. This family of proteins includes several small closely related proteins that bind to CDK4 and CDK6 monomers, blocking their interaction with cyclin D and thus rendering these G_1 CDKs inactive. As we will see in Section 19.4, these G_1 CDKs play an especially important role in the regulation of the G_1–S phase transition, and its integration with extracellular signals.

A second class of CKIs found in metazoan cells is the Cip/Kip family of CKIs. This family consists of three proteins — $p21^{CIP1}$, $p27^{KIP1}$, and $p57^{KIP2}$. The Cip/Kip family members bind to cyclin-bound CDKs and block the activity of cyclin D-, E-, A-, and B-containing complexes. Cip/Kip CKIs must be sequestered away from their respective cyclin/CDK targets or degraded in order for DNA replication or mitosis to commence. Each of the three proteins appears to play a unique physiological role. The $p21^{Cip1}$ protein, encoded by the *cdkn1a* gene, is important in establishing G_1 and G_2 arrest in metazoan cells in response to DNA damage, and its transcription is controlled by the important tumor suppressor protein p53. The $p27^{Kip1}$ protein, encoded by the *cdkn1b* gene, is critical for blocking progression from G_1 into S phase in response to

nutrient and growth factor limitation in order to limit organ and body size. Mice in whom the $p27^{Kip1}$ gene has been knocked out display increased body size and multiple organ hyperplasia (i.e., an excessive number of cells in their organs). The $p57^{Kip2}$ protein, encoded by the *cdkn1c* gene, plays an important role in regulating the cell cycle during embryonic development. Mouse embryos lacking *cdkn1c* display organ hyperplasia and impaired tissue differentiation, resulting in death soon after birth. Based on the crystal structure of $p27^{Kip1}$ bound to cyclin A-CDK2, the Cip/Kip proteins are thought to function both by blocking the site on the cyclin that interacts with cyclin-CDK substrates and occluding the active site cleft to block ATP binding and catalytic activity (see Figure 19-12). These proteins have other functions beyond cell cycle control, including effects on gene transcription, cell fate determination, cell migration, and apoptosis. Nonetheless, the Cip/Kip family members play critical roles in proper cell and tissue homeostasis.

Cyclin Levels Are Regulated by Transcriptional Activation and Ubiquitin-Mediated Protein Degradation

The expression and degradation of cyclins are carefully regulated so that the appropriate cyclins are present in the cell cycle stage at which they are needed. In this section, we discuss how cyclin levels are regulated.

Control of cyclin gene transcription is one mechanism that ensures proper temporal expression of the cyclins. In somatic cells and yeast, waves of transcription factor activity help establish waves of cyclin activity. A general principle is that an earlier wave of CDK phosphorylation-dependent transcriptional activity helps produce the factors essential to generate a subsequent CDK phosphorylation-dependent transcriptional wave. As we will see in Section 19.4, transcription of G_1/S phase cyclins is promoted by the E2F transcription factor complex that becomes activated at this point in the cell cycle.

A very important mechanism that restricts cyclins to the appropriate cell cycle stage is ubiquitin-mediated, proteasome-dependent protein degradation. Because protein degradation is an irreversible process, in the sense that the protein can be replenished only through de novo protein synthesis, this regulatory mechanism is ideal to ensure that the cell cycle engine is driven forward and that cells cannot go backward in the cell cycle.

Recall from Chapter 3 that ubiquitin-protein ligases, also called *E3-ligases*, transfer ubiquitin from an E2 ubiquitin-conjugating enzyme

to one or more lysine residues on the E3-ligase's substrate proteins, making long polyubiquitin chains that mark these proteins for degradation by proteasomes (see Figure 3-32). Cyclins are degraded through the action of two different E3-ligases, called **SCF** (named after the first letters of its constituent proteins, *S*kp1, *C*ullin, and *F*-box proteins) and the **anaphase-promoting complex** or **cyclosome** (abbreviated as **APC/C** in this chapter). The mechanism of regulation of these two E3 ligases that are so critical for cell cycle control is strikingly different, though both involve protein phosphorylation. In the case of the SCF complex, it is the substrates that are phosphorylated to target them for degradation. In the case of the APC/C, it is the APC/C itself that is phosphorylated, controlling its activity.

SCF controls the G_1/S transition by targeting the G_1 and G_1/S phase cyclins for degradation. SCF controls the G_2/M transition by targeting the CDK inhibitory kinase Wee1, along with the $p21^{Cip1}$ and $p27^{Kip1}$ CDK inhibitory proteins for degradation, as we shall see in more detail shortly. The APC/C, in contrast, becomes activated at the onset of mitosis and remains active through the next G_1 phase of the cell cycle. The APC/C targets both S phase and mitotic cyclins for degradation. Activation of the APC/C during mitosis controls the onset of chromosome segregation at the metaphase-anaphase transition by degrading an anaphase inhibitory protein (as discussed in Section 19.6) and promotes mitotic exit. APC/C activity during G_1 inhibits mitotic and S phase CDKs, which allows replication origins

to be reset so that a new round of replication can take place during the subsequent S phase (as discussed in Section 19.4).

SCF and APC/C are multisubunit ubiquitin-protein ligases that belong to the RING finger family of ubiquitin-protein ligases. Despite the fact that SCF and APC/C belong to the same ubiquitin-protein ligase family, their structures and substrate targeting regulation are quite different. The structures of both complexes are shown in Figure 19-14. These molecular assemblies resemble U- or C-shaped clamps. Human SCF complexes contain three core components and a substrate-targeting F-box protein. As shown in Figure 19-14a and b, the Cul1 subunit forms a central structural scaffold that links RBX1 and Skp1. RBX1 is a RING finger–containing protein that binds the E2 ubiquitin-conjugating enzyme. Skp1 is a bridging protein that binds the F-box protein. A number of different interchangeable F-box proteins bind to Skp1, and each one recruits a distinct set of substrate proteins to the SCF, where they are ubiquitinated and targeted for destruction.

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

FIGURE 19-14 E3 ubiquitin ligases control cell cycle progression. (a) SCF ligases are built from a central Cullin scaffold (Cul1) with a RING finger–containing Rbx1 protein and an E2 ubiquitin-conjugating enzyme at one end, and a Skp1 protein bound to an F-box substrate-targeting protein at the other. In this example, the F-box protein is Skp2, which uses a series of leucine-rich repeats to bind to target proteins only when they are phosphorylated. (b) This general architecture is conserved in all SCF ligases, but different phosphoserine/threonine-binding F-box proteins determine the substrate specificity. (c) The APC/C E3 ligases are assembled from 13 or 14 subunits, which are organized like SCF complexes into scaffolding (green), substrate-binding (yellow), and catalytic (red) functions. (d) The APC/C is inactive until it binds to one of the substrate-targeting co-activators, either Cdc20 or Cdh1. This binding activates the catalytic components and positions the Cdc20- or Cdh1-bound target protein for conjugation to ubiquitin (orange triangles).

The anaphase promoting complex or cyclosome (APC/C) consists of 14 core subunits in metazoans and 13 core subunits in yeast, together with one of two related substrate-targeting factors called *Cdc20* and *Cdh1* (Figure 19-14c and d). The activity of APC/C is entirely dependent on binding of the core complex to one of these two substrate-targeting subunits. At the metaphase to anaphase transition, APC/C bound to Cdc20 targets cyclins A and B for degradation, while during anaphase, APC/C bound to Cdc20 ubiquitinylates proteins that inhibit chromosome segregation. During late anaphase, telophase and G_1, APC/C bound to Cdh1 targets different substrates for degradation. Like SCF complexes, the APC/C core is organized into three modules (Figure 19-14c): a scaffold module that structurally organizes the entire complex, a catalytic module that accepts activated ubiquitin from an E2 enzyme, and a substrate recognition module that determines which proteins the APC/C will ubiquitinate.

In the absence of phosphorylation, a loop on one of the APC/C core subunits blocks the APC/C binding site for the substrate-targeting subunit Cdc20. Phosphorylation of this loop by mitotic CDKs shifts its position in a similar manner to how phosphorylation activates protein kinases (Section 3.4). This allows Cdc20 to bind and results in the formation of an active $\mathrm{APC/C}^{\mathrm{Cdc20}}$ complex that can ubiquitinate and target cyclins A and B for degradation, thereby shutting off mitotic CDK activity. Mitotic CDKs also phosphorylate the Cdh1 substrate-targeting subunit, which prevents it from

competing with the Cdc20 subunit for binding during metaphase and early anaphase. After $\mathrm{APC/C}^{\mathrm{Cdc20}}$ targets the mitotic cyclins for degradation, the APC/C and Cdh1 become dephosphorylated through the action of protein phosphatases, particularly PP2A in vertebrate cells or Cdc14 in yeast, preventing Cdc20 binding but instead allowing Cdh1 to bind and form an active $\mathrm{APC/C}^{\mathrm{Cdh1}}$ E3-ligase complex in late anaphase that persists until late G_1 of the next cell cycle.

Substrate-targeting subunits of the APC/C recognize specific sequence motifs on the proteins that the APC/C ubiquitinates. One motif, the destruction box or D-box, has the consensus sequence RXXLX[D/E]ΦΦΦXN[N/S], where X stands for any amino acid, Φ means any hydrophobic amino acid, and the brackets indicate that either of the two amino acids is found at that position in the sequence. Experimentally mutating or deleting the destruction box in mitotic cyclins prevented their ubiquitination and blocked cells from exiting mitosis, demonstrating that mitotic exit requires degradation of mitotic cyclins.

Phosphoserine/Threonine-Binding Domains Build Feedback Loops That Coordinate CDK Activation and Cell Cycle Progression

The final molecular components that we need to discuss in order to understand cyclin-CDK regulation are phosphoserine/threonine-binding domains. We have seen that phosphorylation by protein kinases plays an inordinately important role in controlling cyclin abundance, cyclin degradation, and CDK activity. While some of this regulation is a direct consequence of allosteric changes in the shapes of the phosphorylated proteins themselves, another important way that protein phosphorylation regulates the cell cycle is through the creation of short phosphoserine- or phosphothreonine-containing sequence motifs that are targeted for recognition by phospho-binding proteins or protein domains. The functions of these phosphoserine/threonine-binding domains are summarized in Table 19-1.

These phosphoserine/threonine-binding proteins and modules orchestrate nearly all aspects of cell cycle control. In the most general sense, binding of phosphoserine/threonine-binding domains to CDK substrates or to proteins that control CDK activation works by either targeting the bound proteins to specific subcellular locations, altering their three-dimensional conformation, changing their activity, or targeting them for specific modifications such as additional phosphorylation or ubiquitin-mediated destruction. One example of this is found in the F-box proteins that comprise the substrate-targeting subunits of SCF ligases mentioned previously. Many F-box proteins contain modular phosphoserine/threonine-binding domains that bind to a substrate only if the substrate contains a specific phosphoserine/threonine-containing sequence.

Thus the substrate protein is targeted for ubiquitination and degradation only if it has been phosphorylated previously by a protein kinase. As we will see in the next section, CDK-mediated phosphorylation of a CDK inhibitor can target it for SCF-mediated degradation, leading to more CDK activity, followed by additional CKI degradation, creating a feed-forward loop that amplifies total CDK activity. Other phosphoserine/threonine-binding molecules, including 14-3-3 proteins that regulate the cell cycle, Cks proteins that promote CDK phosphorylation, a proline isomerase called *Pin1* that changes the activity of phosphorylated cell cycle regulators, Polo-box domains that target Polo kinase 1 to its substrates in mitosis, and FHA and BRCT domains that provide surveillance for DNA damage and control cytokinesis. These phospho-binding modules are necessary to form the positive and negative feedback loops that control progression through the cell cycle (Section 19-6) and for surveillance mechanisms that stop the cell cycle in response to catastrophic events (Section 19-7). The importance of being able to specifically recognize short sequences created by protein kinases as a mechanism of cell cycle control is evident from the fact that many different types of protein structures are capable of this type of phospho-specific binding, indicating that the phospho-binding function likely arose in these different proteins by convergent evolution.

Mass Spectrometry Studies and Genetically Engineered CDKs Led to the Discovery of New CDK Substrates and Functions

Different CDKs initiate different cell cycle phases by phosphorylating specific proteins. It is now clear that CDKs phosphorylate a myriad of substrates, thereby directly initiating all aspects of a given cell cycle phase.

In recent years, there have been systematic efforts to identify all of the CDK substrates. The challenge in identifying the substrates of a particular kinase is to distinguish one kinase's phosphorylation events from those carried out by other kinases. Examination of mapped phosphorylation sites on known substrates of cyclin-CDKs and studies using synthetic peptides have revealed that cyclin-CDK complexes preferentially phosphorylate serine and threonine residues when they are found within the consensus sequence [S/T]PX[R/K]K where [S/T] (labeled the P0 position) is the site of CDK phosphorylation, and the sequence contains either an arginine or lysine in the P3 position, a lysine in the P4 position, or both.

A breakthrough in understanding which proteins are targets of CDKs was facilitated by the engineering of a CDK mutant that uses an ATP analog that is not bound by other kinases. The ATP analog has a

bulky benzyl group attached to N_6 of the adenine, which makes the analog too large to fit into the ATP-binding pocket of wild-type protein kinases. However, the ATP-binding pocket of the mutant CDK accommodates this N_6-benzyl ATP analog. Consequently, only the mutant CDK can use this ATP analog as a substrate for transferring its γ phosphate to a protein side chain. When the N_6-benzyl ATP analog with a thiol-labeled γ phosphate was incubated with cell extracts containing a recombinant mitotic CDK with the altered ATP-binding pocket, multiple proteins were labeled and then purified and identified by mass spectrometry (Figure 19-15). In yeast, this procedure identified most of the known CDK substrates plus more than 150 additional yeast proteins.

FIGURE 19-15 Identification of CDK substrates using genetically engineered CDK mutants. (a) The ATP-binding pocket of CDKs was engineered to accept a bulky N_6-benzyl ATP analog also containing a sulfur atom in place of a γ phosphate oxygen atom. Substrates of the mutant kinase that have been labeled with the ATP analog will contain a sulfur atom. (b) After protease digestion of cell proteins, the sulfur-containing peptides are purified using iodoacetamide beads (which bind sulfur), and the peptides are identified using mass spectrometry.

We have now discussed all of the core components necessary for the cell to circumnavigate around the cell cycle: cyclins, CDKs, the phosphoserine/threonine motifs that CDKs create on their substrates, transcription factors, other protein kinases,

phosphatases, CKIs, E3 ligases and the sequence motifs that they recognize, and phospho-binding proteins and domains. In the following sections, we see how these components work together to enable the cell to transition from one stage of the cell cycle to the next. We also describe the critical events that occur during each stage of the cell cycle.

KEY CONCEPTS OF SECTION 19.3

Cell Cycle Progression and Control: Feedback Loops and Post-Translational Modification

- Cyclin-dependent kinases are activated by cyclin subunits. Their activity is controlled at multiple levels.
- Different cyclin subunits activate CDKs at different cell cycle stages. Cyclins are present only in the cell cycle stages that they promote.
- Activating and inhibitory phosphorylation of the CDK subunit contributes to the regulation of CDK activity.
- CDK inhibitors (CKIs) inhibit CDK activity by binding directly to the cyclin-CDK complex.
- Protein degradation is the key mechanism responsible for restricting cyclins to the appropriate cell cycle stage. This degradation is mediated by the ubiquitin-proteasome system and the ubiquitin-protein ligases APC/C and SCF.
- Phosphoserine/threonine-binding proteins and modular domains are used to construct positive feed-forward and negative feedback loops that allow rapid activation and inactivation of CDK activity by binding to CDK regulators and substrates.
- CDKs initiate every aspect of each cell cycle stage by phosphorylating many different target proteins. Systematic efforts using protein kinases engineered to bind only modified forms of ATP have led to the identification of many of these substrates.

19.4 The Transition from G_1 into S Phase and DNA Replication

The previous section described the multiple mechanisms that control the different cyclin-CDK complexes. In this and the following two sections, we examine each cell cycle stage carefully and discuss how it is induced and controlled. We examine how cells initiate DNA replication and mitosis and how chromosomes are segregated. We focus on how cyclin-CDK complexes and other key cell cycle regulators affect each cell cycle phase, and we examine the mechanisms that coordinate their activities. This section investigates how cells decide whether or not to undergo cell division, the molecular basis for the transition from G_1 into S phase, and how DNA replication is initiated. We begin with yeast.

The G_1/S Transition in Budding Yeast Is Controlled by Cyclin-CDK Complexes

The process of cell cycle entry is particularly well understood in budding yeast, and it was in this organism that the molecular mechanisms underlying this cell cycle transition were initially elucidated.

Recall from Section 19.1 that the decision to enter S phase occurs late in G_1 and requires the accumulation of a labile R-factor that

drives the cells through the restriction point, called *START* in yeast. Elegant genetic experiments identified temperature-sensitive mutants in budding yeast that arrest in G_1, failing to form a bud and to initiate DNA replication. One group of these mutants was in the gene encoding the yeast CDK. (As mentioned earlier, budding yeast has only one CDK that triggers all cell cycle transitions and is known as *CDC28*.) This observation proved that CDK activity is essential for entry into S phase. A second set of mutants involved the gene for the labile R-factor, which turned out to be the yeast G_1 cyclin known as *CLN3*. We now know that a CDK cascade triggers further progress from G_1 through S phase in yeast (Figure 19-16a). The G_1 cyclin-CDK complex (Cln3-CDK in yeast) stimulates the formation of G_1/S phase cyclin-CDKs, which initiate bud formation, centrosome duplication, and DNA replication. The mRNA for the yeast G_1 cyclin gene *CLN3* is produced at a nearly constant level throughout the cell cycle, but its translation is regulated in response to nutrient levels and, as we will see shortly, it is a linchpin in coupling cell cycle entry to nutrient signals. Once sufficient Cln3 is synthesized from its mRNA, Cln3-CDK complexes phosphorylate and inactivate the transcriptional repressor Whi5. Phosphorylation of Whi5 promotes its export out of the nucleus, allowing the transcription factor complex SBF to induce transcription of the G_1/S phase cyclin genes *CLN1* and *CLN2* as well as other genes important for DNA replication. Once produced, Cln1/2-CDKs contribute to further Whi5 phosphorylation. This positive feedback loop ensures the rapid accumulation of G_1/S phase cyclin-CDKs. The point in the cell cycle at which 50 percent of

Whi5 has exited the nucleus marks the point when cells are irreversibly committed to division and provides a molecular definition of START. Cln1/2-CDKs then trigger bud formation, entry into S phase, and the duplication of the centrosome (also known as the *spindle pole body* in yeast), which will organize the mitotic spindle.

FIGURE 19-16 Control of the G_1–S phase transition. (a) In budding yeast, activity of the G_1 cyclin–CDK Cln3-CDK rises during G_1 and is controlled by nutrient availability. Once sufficiently active, the kinase phosphorylates the transcriptional repressor Whi5, promoting its export from the nucleus. This releases the transcription factor complex SBF, allowing it to induce the transcription of the G_1/S phase cyclin genes *CLN1* and *CLN2* and of other genes whose products are needed for DNA replication. G_1/S phase CDKs further phosphorylate Whi5, promoting further *CLN1* and *CLN2* transcription. Once sufficiently high levels of G_1/S phase CDKs have been produced, START is traversed. Cells irreversibly enter the cell cycle: they initiate DNA replication, bud formation, and spindle pole body duplication. (b) In vertebrates, G_1 CDK activity rises during G_1 and is stimulated by the presence of growth factors. When signaling from growth factors is sustained, the resulting cyclin D–CDK4/6

complexes begin phosphorylating Rb, releasing some E2F, which stimulates transcription of the genes encoding cyclin E, CDK2, and E2F itself. The cyclin E–CDK2 complexes further phosphorylate Rb, resulting in a positive feedback loop that leads to a rapid rise in the expression and activity of both E2F and cyclin E–CDK2. Once G_1/S phase CDKs are sufficiently high, cells pass through the restriction point; they irreversibly commence DNA replication and centrosome duplication.

The G_1–S Phase Transition in Metazoans Involves Cyclin-CDK Control of the E2F Transcription Factor Through Its Regulator Rb

The sequence of events we described in yeast is similar in mammalian — and in fact all metazoan — cells. Growth factor signaling through the mitogen-activated protein kinase (MAPK) pathway triggers increased transcription of the G_1 cyclins, members of the cyclin D family. As long as levels of the Ink4 CKI family members are low, cyclin D binds to the G_1 CDKs, CDK4 and CDK6, to form active G_1 cyclin-CDK complexes. In turn, these G_1 CDKs activate members of a small family of related transcription factors, referred to collectively as **E2F transcription factors (E2Fs)**. During G_1, the E2Fs are maintained in an inactive state through tight association with the retinoblastoma protein (Rb; Figure 19-16b). When G_1 CDKs become activated, they phosphorylate Rb, causing it to dissociate from the E2Fs. Released E2Fs then activate genes

encoding many of the proteins involved in DNA synthesis. Thus the E2Fs have a function in late G_1 that is similar to that of the *S. cerevisiae* transcription factor complex SBF [compare (a) and (b) in Figure 19-16]. The E2Fs also stimulate transcription of genes encoding the G_1/S phase cyclin, cyclin E, and the S phase cyclin, cyclin A. Cyclin E forms a complex with the G_1/S CDK, CDK2, which then further phosphorylates Rb in a positive feedback loop, much like how the Cln1/2-CDK complex further phosphorylates Whi5 in yeast (Figure 19-16), to reinforce S phase entry.

As noted above, key to the regulation of E2F function is the Rb protein. When E2Fs are bound to Rb, not only are they transcriptionally inactive, but they also function to repress transcription. This is because Rb recruits chromatin-modifying enzymes that promote deacetylation and methylation of specific histone lysines, causing chromatin to assume a condensed, transcriptionally inactive form (see Section 8.5). *RB* was initially identified as the gene mutated in retinoblastoma, a childhood cancer of the retina. Subsequent studies found Rb to be inactivated in many cancers, either by mutations in both alleles of *RB* or by abnormal regulation of Rb phosphorylation (see Chapter 25).

Rb protein regulation by G_1 CDKs in mammalian cells is analogous to Whi5 regulation by Cln3-CDK in yeast. Phosphorylation on multiple sites by G_1 CDKs blocks Rb from associating with E2F and promotes its export out of the nucleus. This allows E2F to activate

the transcription of genes required for entry into S phase. Once the expression of genes coding for the G_1/S cyclins and CDK has been induced by phosphorylation of some of the Rb molecules, the resulting G_1/S phase CDK complexes further phosphorylate Rb in late G_1. This is one of the principal biochemical events responsible for passage through the restriction point (Figure 19-16b). Since E2F stimulates its own expression as well as that of the G_1/S cyclin-CDKs, cross-regulation of E2F and G_1/S cyclin-CDKs through a positive feedback loop produces a rapid rise of both activities in late G_1.

As they accumulate, S phase CDKs as well as mitotic CDKs maintain Rb protein in the phosphorylated state throughout the S, G_2, and early M phases. After cells complete anaphase and enter early G_1 or G_0, a fall in all cyclin-CDK activities leads to the de-phosphorylation of Rb. As a consequence, poorly phosphorylated Rb is available to inhibit E2F activity during early G_1 of the next cycle and in G_0-arrested cells. Thus G_1/S phase CDK activity remains low until cells decide to enter a new cell cycle and G_1 CDKs break the inhibitory grip of Rb on E2F.

Extracellular Signals Govern Cell Cycle Entry

Whether or not cells enter the cell cycle is influenced by extracellular as well as intracellular signals. Unicellular organisms such as yeasts, for example, enter the cell cycle only when they have reached an appropriate size, known as the **critical cell size**. This critical size, in turn, is controlled by nutrients available in the environment. Here we restrict our discussion to the fact that G_1 cyclin synthesis is responsive to the rate of protein synthesis, which is in turn controlled by pathways that are regulated by nutrients in the environment. This link between the macromolecule biosynthesis machinery and the cell cycle machinery is well understood in budding yeast. In this organism, the G_1 cyclin transcript *CLN3* contains a short upstream open reading frame that inhibits translation initiation when nutrients are limited. This inhibition is diminished when nutrients are in abundance. In the presence of sufficient nutrients, the TOR signaling pathway, which senses nutrients and growth factor signals, is active and stimulates translational activity (see Figure 21-3b). Since Cln3 is an unstable protein, its concentration fluctuates with the translation rate of its mRNA. Consequently, the amount and activity of Cln3-CDK complexes, which depend on the concentration of Cln3 protein, are regulated by nutrient levels.

In multicellular organisms, cells are surrounded by nutrients, and as such, nutrients do not usually limit the rate of cell proliferation. Rather, cell proliferation is controlled by the presence of growth-promoting factors (**mitogens**) and growth-inhibiting factors (*anti-*

mitogens) in the cell surroundings. As discussed in Chapter 16, addition of mitogens to G_0-arrested mammalian cells induces receptor tyrosine kinase–linked signal transduction pathways that initiate signal transduction cascades. These signaling cascades ultimately influence transcription and cell cycle control. They do so in multiple ways.

Mitogens activate the transcription of multiple genes. Most of these genes fall into one of two classes — *early response* or *delayed response* genes — depending on how soon their encoded mRNAs appear. Transcription of early response genes is induced within a few minutes after addition of growth factors by signal transduction cascades that activate preexisting transcription factors in the cytosol or nucleus (see Chapter 16). Many of the early response genes encode transcription factors, such as c-Fos and c-Jun, that stimulate transcription of the delayed response genes. The early response transcription factor Myc induces the transcription of G_1 cyclin and CDK genes. In addition to being controlled by transcription, G_1 CDKs are regulated by CKIs. The CKI $p15^{INK4b}$ is a potent CDK inhibitor. In some tissues, mitogens inhibit the production of this CKI by inhibiting its transcription.

In many tissues, cell proliferation is also regulated by anti-mitogens, which prevent entry into the cell cycle. Similarly, during differentiation, cells cease to divide and enter G_0. Some differentiated cells (e.g., fibroblasts and lymphocytes) can be

stimulated to re-enter the cell cycle and replicate. Many postmitotic differentiated cells, however, never re-enter the cell cycle to replicate again. Anti-mitogens and differentiation pathways prevent the accumulation of G_1 CDKs. They antagonize the production of G_1 cyclins and induce the production of CKIs. Transforming growth factor β (TGF-β) is an important anti-mitogen. This hormone induces a signaling cascade that brings about G_1 arrest by inducing the expression of $p15^{INK4b}$. As we will see in Chapter 25, the signaling pathways that regulate G_1 CDKs are often mutated in many human cancers.

Degradation of an S Phase CDK Inhibitor Triggers DNA Replication

Entry into S phase is defined by the unwinding of origins of DNA replication. G_1/S phase CDKs play an essential role in this process by turning off the machinery that degrades S phase cyclins during exit from mitosis and G_1. In addition, they induce the degradation of a CKI that inhibits S phase CDKs, initiating a rapid transition from low to high S phase CDK activity.

One of the important substrates of the G_1/S phase cyclin-CDK complexes is Cdh1. During late anaphase, Cdh1 directs APC/C to ubiquitinylate substrate proteins, including S phase and mitotic cyclins, marking them for proteolysis by proteasomes (see Figure 19-

14d). This ensures that when cells exit mitosis, they arrive into a G_1 state of low cyclin-CDK activity, allowing them to assess their internal and external environments prior to committing to another round of cell division. The APC/C^{Cdh1} complex remains active throughout G_1, preventing the premature accumulation of S phase and mitotic cyclins. If conditions for another round of cell division are favorable, then a G_1/S cyclin-CDK induced signaling pathway results in phosphorylation of Cdh1, causing it to dissociate from the APC/C complex, inhibiting further ubiquitinylation of S phase and mitotic cyclins during late G_1 and allowing them to progressively accumulate (Figure 19-17). This block in cyclin degradation, combined with the induced transcription of S phase cyclins during late G_1, allows S phase cyclins to accumulate as G_1/S cyclin-CDK levels rise. Later in the cell cycle, S phase and mitotic CDKs take over to maintain Cdh1 in the phosphorylated, and hence inactive, state. Only as mitotic CDKs decline and a protein phosphatase in yeast known as *Cdc14* becomes activated are these inhibitory phosphates removed from Cdh1, leading to its reactivation, again targeting mitotic proteins including M and S phase cyclins for degradation. In mammalian cells, similar mechanisms are responsible for stabilizing S phase and mitotic cyclins, but the phosphatase(s) involved in de-phosphorylation of Cdh1 have not been identified.

FIGURE 19-17 Regulation of S phase and mitotic cyclin levels in budding yeast. In late anaphase, the anaphase-promoting complex (APC/C) ubiquitinylates S phase and mitotic cyclins. The activity of this ubiquitin-protein ligase is directed toward mitotic cyclins by a specificity factor called *Cdh1*. Cdh1 activity is regulated by phosphorylation. During exit from mitosis and G_1, Cdh1 is de-phosphorylated and APC/C^{Cdh1} is active. During S phase and mitosis, Cdh1 is phosphorylated, Cdh1 dissociates from APC/C, and APC/C becomes inactive. The G_1/S phase CDKs, which themselves are not APC/C^{Cdh1} substrates, phosphorylate Cdh1 at the G_1–S phase transition. A specific yeast phosphatase called *Cdc14* removes the regulatory phosphate from the specificity factor late in anaphase.

In *S. cerevisiae*, as S phase cyclin-CDK accumulates in late G_1, they are immediately inactivated by binding of a CKI called *Sic1* that is expressed late in mitosis and early in G_1 (Figure 19-18a). Because Sic1 specifically inhibits S phase and M phase CDK complexes but has no effect on the G_1 CDK and G_1/S phase CDK complexes, it functions as an S phase inhibitor. Initiation of DNA replication occurs when the Sic1 inhibitor is precipitously degraded following

its ubiquitinylation by the SCF ubiquitin-protein ligase (see Figure 19-14a).

FIGURE 19-18 Switch-like control of S phase onset in *S. cerevisiae* by phospho-regulated proteolysis of the S phase inhibitor Sic1. (a) The S phase cyclin-CDK complexes begin to accumulate in G_1 but are inhibited by Sic1. This inhibition prevents initiation of DNA replication until the cells have completed all G_1 events. G_1/S phase CDKs assembled in late G_1 phosphorylate Sic1 at multiple sites (step **1**), marking it for phospho-dependent binding and ubiquitinylation by the SCF ubiquitin-protein ligase and subsequent proteasomal degradation (step **2**). The active S phase CDKs then trigger initiation of DNA synthesis (step **3**) by phosphorylating and recruiting MCM helicase activators to DNA

replication origins (not shown). (b) A single optimal G_1/S phase CDK phosphorylation site in Sic1 that was strongly recognized by the phospho-binding F-box in SCF ubiquitin-protein ligase would result in a sluggish G_1–S phase transition. As G_1/S phase CDKs accumulate during G_1, Sic1 would be progressively degraded. As a result, S phase CDKs would slowly rise, and initiation of S phase would be a drawn-out event. (c) Six suboptimal phosphorylation sites in Sic1 create a switch-like cell cycle entry. Only when all of the suboptimal sites in Sic1 are fully phosphorylated is the protein recognized by the phospho-binding F box in SCF. This can only occur when G_1/S phase CDKs have reached high levels. This ensures that Sic1 degradation occurs rapidly, and only when G_1/S phase CDKs have accomplished all their other G_1 tasks. See P. Nash et al., 2001, *Nature* **414**:514–521; and D. O. Morgan, 2006.

Degradation of Sic1 is induced by its phosphorylation by G_1/S phase CDKs (Figure 19-18a). It must be phosphorylated at no fewer than six sites, each of which is a relatively poor substrate for the G_1/S phase CDKs, before it is bound sufficiently well by SCF to be ubiquitinylated. In contrast, if Sic1 were inactivated following the phosphorylation of a single site, Sic1 molecules would start to get phosphorylated and degraded as soon as the levels of G_1/S phase CDK activity begin to rise, leading to a gradual decrease in Sic1 levels (Figure 19-18b) and poor control over S phase entry. Because six sites need to be phosphorylated, at low levels of G_1/S phase CDK activity Sic1 is only partially phosphorylated and Sic1 is not destroyed. Only when G_1/S phase CDK levels are high is Sic1 sufficiently phosphorylated to target it for degradation. Having multiple suboptimal phosphorylation sites therefore leads to an ultrasensitive, switch-like response in Sic1 degradation and hence precipitous activation of S phase CDKs (Figure 19-18c). Sic1

degradation occurs only when G_1/S phase CDK activity has reached its peak and virtually all the other G_1/S phase CDK substrates have been phosphorylated.

An obvious advantage of proteolysis for controlling passage through this critical point in the cell cycle is that protein degradation is an *irreversible process*, ensuring that cells proceed in one direction through the cycle.

Entry into S phase in metazoan cells is regulated by a switch-like mechanism similar to that in budding yeast. Like Sic1, the CKI p27 binds to and prevents the premature activation of S phase CDKs during G_1. Unlike Sic1, however, this CKI inhibits both S phase CDKs and G_1/S phase CDKs. Like Sic1 in yeast, p27 is removed from cyclin-CDK complexes by ubiquitin-dependent protein degradation and a pathway, analogous to the one operating on Sic1, targets p27 for degradation at the G_1–S phase transition. As G_1/S phase CDKs and S phase CDKs reach high levels during late G_1 and early S phase, they begin to phosphorylate p27, targeting it for ubiquitinylation by SCF^{SKP2}. Degradation of p27 causes activation of G_1/S phase and S phase CDKs. These kinases then initiate S phase by phosphorylating proteins important for the initiation of DNA replication.

Replication at Each Origin Is Initiated Once and Only Once During the Cell

Cycle

As discussed in Chapter 5, eukaryotic chromosomes are replicated from multiple replication origins, specific sites on the chromosomes where the replication machinery is assembled, and where the copying of the two strands of DNA begins. Replication of all of the chromosomal DNA — starting from these origins — occurs during S phase. Each eukaryotic origin fires only once per S phase to initiate replication from that site, and S phase continues until replication from each of the multiple origins that lie along the length of each chromosome has resulted in complete replication of the entire chromosome. The DNA that is copied from a single origin is called a *replicon*. This process of creating and fusing the replicons ensures that each DNA strand is copied only once, maintaining the correct gene copy number each time a cell replicates.

S phase CDKs play an essential role regulating DNA replication. As we shall see in more detail shortly, these kinases allow DNA replication to be initiated only at the G_1–S phase transition and prevent re-initiation from origins that have already fired. We first discuss how initiation of DNA replication is controlled, and the role of S phase CDKs in the process, before turning to the mechanisms these kinases use to prevent re-initiation.

The powerful genetic methods available for experimental manipulation of budding yeast have led to the identification of specific mutants defective in DNA replication. Consequently, we

have a fairly comprehensive understanding of the mechanisms by which yeast initiates and implements DNA replication. Although many details differ between yeast and mammalian cells, the basic processes are essentially the same, so we will focus our discussion first on how DNA replication is accomplished in budding yeast. It is important to remember that the five basic steps of genome replication are essentially the same in all eukaryotic species (Figure 19-19). The steps are: (1) recognizing the replication origins; (2) assembling replication initiation factors that then load a replicative helicase in order to form a so-called prereplication complexes, or pre-RCs; (3) recruiting critical helicase cofactors; (4) activation of the helicase to unwind the two DNA strands; and (5) recruitment of the replicative DNA polymerase machinery (i.e., the "replisome") that then copies each strand.

FIGURE 19-19 The molecular mechanisms governing the initiation of DNA replication. Step 1: During exit from mitosis and early G_1, when CDK activity is low, ORC recognizes and binds to replication origins. In step 2, the MCM loading factors Cdc6, and Cdt1 load the inactive replicative helicase, the MCM complex, onto DNA at replication origins, forming the pre-RC complex. Step 3: Activation of S phase CDKs and DDK marks the onset of S phase. They phosphorylate the MCM helicase, Sld2, and Sld3 (depicted as yellow phosphorylation events), to facilitate the loading of MCM helicase activators — the Cdc45 and GINS complexes — onto sites of replication initiation. Step 4: Loading of these activators leads MCM helicases to unwind DNA. S phase CDKs also prevent reloading of MCM helicases by phosphorylating Cdc6 and Cdt1 promoting their release from the replication origins and their nuclear export or degradation by ubiquitin ligases. S phase CDKs also phosphorylate MCM helicases (depicted as orange phosphorylation events), which leads to their export from the nucleus when the helicases disengage from the DNA when

replication is complete. Step **5**: The additional DNA polymerases Pol α (the primase) and Pol δ, along with the processivity factor PCNA, are recruited to origins, which leads to the initiation of DNA replication on both the leading and lagging strands (see Figure 5-30).

[Data from Y. Li and H. Araki, 2013, *Genes Cells* **18**:266–277.]

Even though DNA replication will not occur until S phase, the first 2 steps actually occur in G_1 phase, when the activity of G_1 and S phase CDKs is low. As shown in Figure 19-19, in step **1**, a complex of six proteins known as the *origin-recognition complex (ORC)* binds to all of the DNA replication origins. In budding yeast, an ORC binds to an 11-bp conserved core sequence found in every replication origin. The situation is more complicated in multicellular organisms because DNA replication origins lack any recognizable consensus sequence. Instead, it is thought that additional chromatin-associated factors target ORC to the DNA at replication origins. Once bound to DNA, ORC is thought to function as a landing pad for the assembly of additional factors necessary for DNA replication to commence. During step **2**, two replication initiation factors, Cdc6 and Cdt1, bind to ORC at the origins and then proceed to load another complex of six proteins, known as the *MCM helicase* (for *m*ini *c*hromosome *m*aintenance), onto the DNA to form a pre-RC. The MCM complexes appear to be loaded as double hexamers facing in opposite directions, allowing DNA unwinding to progress in both directions from the origins. Once loaded onto the origin DNA in G_1 phase, the helicases remain inactive until the cell has entered S phase. This restriction on activity is conferred by CDKs, which regulate two

opposing phosphorylation states. The MCM helicases can only be loaded onto the DNA in a state of low CDK activity that occurs when CDKs are inactivated during exit from mitosis and during early G_1. In other words, MCM helicases are loaded onto DNA to form pre-RCs only when they are nonphosphorylated. In contrast to DNA loading, activation of the MCM helicases and the recruitment of DNA polymerases to the unwound origin DNA can only occur when the MCM helicase proteins are phosphorylated. This happens only in S phase, when they are phosphorylated by S phase CDKs and a second protein kinase called *DDK* (for *D*bf4-*d*ependent *k*inase).

Just like CDKs, which require cyclin-binding for activity, the monomeric DDK kinase subunit (also known as *Cdc7*) is inactive in its monomeric form. Only when DDK binds to the Dbf4 subunit does it acquire kinase catalytic activity. During G_1, the Dbf4 protein is continuously targeted for degradation by the APC/C. Only during S phase, when the APC/C is inactivated by CDK phosphorylation, does Dbf4 accumulate and activate DDK. (Recall that S phase CDKs become active only when G_1/S phase CDK levels reach their peak, allowing the CKIs of S phase CDKs to be destroyed.) Putting all of this phosphorylation and ubiquitination-mediated control together, the key concept that emerges is that the increase in CDK and DDK activity during S phase enforces the strict temporal separation of pre-RC formation (i.e., loading of the MCM helicases), which only happens during G_1, from firing of the origins to start DNA replication, which only happens during S phase. Formation of the

pre-RCs is sometimes referred to as *replication licensing*, meaning that the MCM-loaded origins are now licensed to fire later in S phase. By only licensing origins during G_1 (Figure 19-19, steps **1** and **2**), and only firing origins during S phase (Figure 19-19, steps **3**–**5**), the cell ensures that each origin only triggers DNA replication once with each passage through the cell cycle, thereby preventing inappropriate genomic re-replication.

So how do S phase CDKs and DDK collaborate at the mechanistic level to initiate DNA replication and prevent re-replication? The process is rather complicated, and the exact order of events differs somewhat between yeast and metazoans, but the basic concept, which is the same in all cells, is to recruit helicase cofactors (step **3**) that will activate the MCM helicases (step **4**) at the same time that the replicative polymerase machinery (the replisome) is loaded onto the DNA (step **5**). This coordination prevents excessive unwinding of DNA, which would result in the accumulation of large amounts of single-stranded DNA. The activation process involves binding of inactive MCM helicase to two other protein complexes, one containing Cdc45 and the other containing GINS, in order to form the active Cdc45-MCM-GINS (CMG) helicase complex. Formation of the CMG complex requires phosphorylation events catalyzed by both DDK and S phase CDKs, which are activated in late G_1. In yeast it happens like this: DDK phosphorylates the N-termini of several subunits of the MCM helicase, altering their conformation, and leading to the recruitment of one of the two

critical MCM helicase cofactors, a protein known as *Cdc45*. Cdc45 is required for MCM helicase activity, and binds to the MCM helicase as part of a complex with two other proteins Sld3 and Sld7 (Figure 19-19, step **3**). Sld3 recruits another protein complex containing Pol ε (the replicative polymerase that synthesizes the leading strand), forming a fully active CMG helicase. The origins unwind (Figure 19-19, step **4**), Pol α (the primase), Pol δ (the replicative polymerase that synthesizes the lagging strand), and PCNA (the DNA sliding clamp that holds the polymerases anchored to the DNA to increase processivity) then bind, and replication ensues (Figure 19-19, step **5**).

S phase CDKs are not only essential for initiating DNA replication but also are responsible for ensuring that each origin fires only once during S phase. Refiring of origins during S phase is prevented by phosphorylation of several components of the MCM helicase-loading machinery and the MCM helicase complex itself. To distinguish these phosphorylation events from the ones required for the initiation of DNA replication, they are depicted in orange in Figure 19-19. Concomitant with activation of the MCM helicases, Cdc6 and Cdt1 dissociate from the sites of DNA replication initiation. Once they have done so, their phosphorylation leads to export of Cdt1 from the nucleus, and degradation of Cdc6 by the SCF ubiquitin-protein ligase in yeast. Phosphorylation of MCM helicases leads to the export of these proteins from the nucleus after they dissociate from the DNA on completion of DNA replication. Thus

only after CDK activity is lowered by APC/C^{Cdh1} during exit from mitosis can MCM helicases be reloaded onto DNA. As a result, helicase loading is restricted to late stages of mitosis and early G_1 (see Figure 19-19, steps **1** and **2**).

The general mechanisms governing the initiation of DNA replication in metazoan cells parallel those in *S. cerevisiae*, although some differences are found in vertebrates. The helicases are loaded in G_1, when CDK activity is low. Phosphorylation of MCM helicase activators by G_1/S phase CDKs and S phase CDKs activates the helicases and promotes polymerase loading. As in yeast, phosphorylation of the MCM helicase-loading factors Cdc6 and Cdt1 prevents reloading of MCM helicases until the cell passes through mitosis, thereby ensuring that replication from each origin occurs only once during each cell cycle. In addition, vertebrates contain a small protein, geminin, that also contributes to the inhibition of re-initiation at origins until cells complete a full cell cycle. Geminin is expressed in late G_1; it binds to and inhibits Cdt1 (see Figure 19-19, step **2**), thereby preventing reloading of the MCM helicase that is released from origins after DNA replication is initiated during S phase. Geminin contains a destruction box at its N-terminus that is recognized by APC/C^{Cdh1}, causing it to be ubiquitinylated in late anaphase and degraded by proteasomes. Its degradation frees the MCM helicase-loading factors, which are also de-phosphorylated as CDK activity declines, to bind to ORC on replication origins and load MCM helicases during the following G_1 phase. During S phase, the

combined ubiquitin-mediated degradation of Cdt1 and the inactivation of any residual Cdt1 left over by geminin provides redundant regulation to ensure that there is no accidental chromosome re-replication.

Duplicated DNA Strands Become Linked During Replication

It is essential that the sister chromatids generated during S phase remain together until they separate during the metaphase-to-anaphase transition of mitosis. As chromosomes are duplicated to form sister chromatids, they become tethered to each other by protein links. The protein ring complexes that establish these linkages between sister chromatids are called **cohesins**. They are composed of four subunits: Smc1, Smc3, Scc1, and Scc3 (Figure 19-20a). Smc1 and Smc3 are members of the structural maintenance of chromosomes (SMC) protein family, which is characterized by globular domains at the N- and C-termini connected by a long α helix. The helix is broken in the middle by a globular hinge domain, so that the two halves of the α helix in each protein fold back on themselves to form a coiled-coil structure. The globular head domains bind and hydrolyze ATP. The ATPase domains interact with the proteins Scc1 and Scc3, which together form a ring structure. These cohesin rings embrace one or both copies of the replicated

DNA. When cohesins are experimentally inactivated, sister chromatids do not associate properly with each other.

FIGURE 19-20 Model for establishment of cohesin linkage of sister chromatids. Cohesin complexes form rings that link sister chromatids by embracing the two sister DNA molecules. (a) Schematic structure of the yeast cohesin complex. The structure of vertebrate

cohesion is essentially the same, though some of the proteins have different names. (b) Mechanism whereby cohesins are loaded onto DNA and acquire their cohesive properties. Step **1**: Cohesins are loaded onto chromosomes during G_1 by the cohesin-loading complex Scc2-Scc4, but the cohesins do not possess cohesive (gluelike) properties. In this state, cohesins are dynamic and can slide along the DNA or dissociate from the DNA with the help of the Pds5-Wapl complex, which associates with cohesins. Step **2**: Concomitant with DNA replication, closely behind the replication fork cohesins are converted into cohesive molecules, able to glue sister chromatids together through acetylation of Smc3 by cohesin acetyltransferases (CoATs). Acetylation, indicated by brown circles on SMC3, is accompanied in vertebrates by the binding of sororin to cohesin, which helps stabilize cohesins on chromosomes. In budding yeast, both sister chromatids are embraced within a single cohesin ring, as shown. (c) Cohesion-independent functions of cohesins during G_1 include partitioning of the genomic DNA into discrete compartments of the nucleus called *topologically associated domains (TADs)* and controlling gene expression by bringing enhancers close to promoters and transcription start sites through chromosomal DNA looping. In combination with CCCTC-binding factor (CTCF), cohesin-looping can activate some genes in a cluster, shown by arrows, while repressing others, indicated by the T symbol.

[Part (c) Information from A. Losada, 2014, *Nat. Rev. Cancer* **14**:389–393.]

Cohesin-mediated cohesion between sister chromatids is established by a two-step process and is tightly tied to DNA replication. In the first step, which occurs during G_1, cohesins associate with chromosomes, aided by cohesin loading factors Scc2 and Scc4 (Figure 19-20b, step **1**). In G_1, the chromosome-cohesin interaction is quite dynamic. In addition to Scc2-Scc4–mediated binding, cohesins are unloaded continuously by a cohesin-associated complex composed of the Pds5 and Wapl proteins. This continual loading and unloading of cohesins is likely to be

important in regulating interphase chromatin structure and gene expression (Figure 19-20c).

Cohesins acquire their cohesive properties during DNA replication. In the second step, the two duplicated DNA strands become entrapped within the cohesin rings as replication forks replicate the DNA (Figure 19-20b, step **2**). Converting DNA-bound G_1 cohesins into cohesive complexes requires acetylation of the Smc3 subunit by cohesin acetyl transferases (CoATs). This acetylation prevents unloading of cohesins by Pds5-Wapl, thereby stabilizing the cohesins on chromosomes. In vertebrates, stabilization of cohesins requires the cohesin-associated factor sororin (Figure 19-20a and b, step **2**). As we will see in Section 19.6, cohesins are essential for accurate attachment of the replicated sister chromatids to the mitotic spindle and for their segregation during mitosis.

Cohesins also regulate the topological localization of chromosomes within the interphase cell nucleus and help control gene expression (Figure 19-20c). In some instances, cohesins promote gene expression, whereas in others they restrain it. The mechanism cohesins use to accomplish gene expression control is, however, the same in both cases: cohesins promote chromatin loop formation, which brings enhancer or repressor elements close to the promoter and transcriptional start site. Defects of cohesin's gene expression regulation function are the cause of a group of diseases collectively called *cohesinopathies*. In these diseases, mutations in

cohesin subunits or cohesin-loading factors disrupt the expression of genes that are critical for development, causing limb and craniofacial abnormalities and intellectual disabilities. Cohesin's sister chromatid cohesion function, however, is intact in these diseases. In contrast, as we will see in Section 19.8, defects in cohesin's cohesion function during meiosis cause miscarriages and intellectual disabilities. ■

KEY CONCEPTS OF SECTION 19.4

The Transition from G_1 into S Phase and DNA Replication

- The molecular events promoting entry into the cell cycle are conserved across species. G_1 CDKs phosphorylate and inhibit a transcriptional repressor. This permits transcription of G_1/S phase cyclin genes and other genes important for S phase (see Figure 19-16).
- Extracellular signals such as nutritional state (in yeast) and the presence of mitogens and anti-mitogens (in vertebrates) regulate entry into the cell cycle.
- Various polypeptide growth factors called *mitogens* stimulate cultured mammalian cells to proliferate by inducing expression of early response genes. Many of these genes encode transcription factors that stimulate expression of genes encoding the G_1/S phase cyclins and E2F transcription factors.
- The G_1/S phase CDKs phosphorylate and inhibit Cdh1, the factor that directs the anaphase-promoting complex (APC/C) to ubiquitinylate S phase and M phase cyclins. This allows S phase cyclins to accumulate in late G_1 (see Figure 19-17).
- In yeast, S phase CDKs are initially inhibited by Sic1. A series of phosphorylation sites marks Sic1 for binding to a phosphoserine/threonine-binding domain on an SCF ubiquitin-protein ligase, leading to its ubiquitinylation and proteosomal degradation. This releases activated S phase CDKs that trigger an abrupt step-like onset of the S phase (see Figure 19-18). A similar phospho-dependent degradation of Cip/Kip CKI proteins functions in a similar manner to control S phase entry in animal cells.
- DNA replication is initiated from helicase loading sites known as *replication origins*.
- Loading and activation of MCM helicases occur in mutually exclusive cell cycle states: MCM helicase loading can occur only when CDK activity is low (during early G_1); MCM

helicases are activated when CDK activity is high (during S phase).

- S phase CDKs and DDK trigger the initiation of DNA replication by recruiting MCM helicase activators to origins (see Figure 19-19).
- Initiation of DNA replication occurs at each origin only once during the cell cycle because S phase CDKs activate the helicases and at the same time prevent additional helicases from loading onto DNA.
- Cohesins establish linkages between the replicated DNA molecules (see Figure 19-20), which are essential for their accurate segregation later in the cell cycle. This linking mechanism is coupled to DNA replication.

19.5 The G_2/M Transition and the Irreversible Engine of Mitosis

Once S phase has been completed and the entire genome has been duplicated, the pairs of duplicated DNA chromosomes — the sister chromatids — are segregated to the future daughter cells. This process requires not only the formation of the apparatus that facilitates this segregation — the mitotic spindle — but essentially a complete remodeling of the cell. Chromosomes condense and attach to the mitotic spindle, the nuclear envelope is disassembled, and almost all organelles are rebuilt or modified. These events are triggered by mitotic CDKs and a handful of other key mitotic kinases, particularly the Aurora kinases and the Polo-like kinases. This section first discusses how the mitotic CDKs are precipitously activated during G_2, following the completion of DNA replication, through a series of positive feedback loops involving the CDKs themselves, together with Aurora kinase A and Polo-like kinase 1 (Plk1). We then describe how these kinases bring about the dramatic changes in the cell necessary to facilitate sister chromatid segregation during anaphase, focusing on the events as they occur in metazoans.

Precipitous Activation of Mitotic CDKs by Positive Feedback Loops Initiates

Mitosis

Mitotic cyclin-CDKs initiate mitosis. Whereas levels of the catalytic CDK1 subunit (the mitotic CDK) are constant throughout the cell cycle, mitotic cyclins gradually accumulate during S phase. Most eukaryotes contain multiple mitotic cyclins, which for historical reasons are subdivided into the cyclin A and cyclin B families. As they assemble, mitotic cyclin-CDK complexes are maintained in an inactive state through inhibitory phosphorylation of the CDK1 subunit. Recall from Section 19.3 that two highly conserved tyrosine and threonine residues in mammalian CDKs are subject to regulated phosphorylation. In CDK1, phosphorylation of threonine 14 and tyrosine 15 maintains mitotic cyclin-CDK complexes in an inactivate state (see Figure 19-12). The phosphorylation state of T14 and Y15 is controlled by a dual-specificity protein kinase known as **Wee1** and a pair of dual-specificity phosphatases, **Cdc25B** and **Cdc25C**). Dual-specificity kinases and phosphatases can phosphorylate and de-phosphorylate serines, threonines, and tyrosines. Their regulation of mitotic CDK1 underlies the abrupt activation of CDK1 kinase activity at the G_2/M phase transition and explains the observation that although mitotic cyclins gradually accumulate during S phase and G_2, mitotic CDKs are not active until cells enter mitosis.

The critical roles of Wee1 and Cdc25 in controlling the entry of G_2 cells into mitosis emerged first from studies in the fission yeast *Schizosaccharomyces pombe*. Recall from Section 19.2 that fission

yeast coordinate cell size and cell division during G_2 (see Figure 19-4). This is in contrast to budding yeast and vertebrate cells, which coordinate cell size and cell division during G_1 and therefore spend most of the cell cycle in this phase. This means that the length of fission yeast at the time they divide is a direct reflection of the duration of G_2. In *S. pombe* the dual-specificity protein kinase Wee1 phosphorylates CDKs on the inhibitory tyrosine 15 (see Figure 19-13). (Threonine 14 is not phosphorylated in *S. pombe* CDK1.) Yeast cells with a defective $wee1^+$ gene activate mitotic CDKs prematurely and hence experience premature entry into mitosis. These wee1 mutants are therefore smaller than normal cells. In fact, the Scottish term for small is "wee," hence the name for this gene that, when mutated, resulted in small cells. Consistent with the importance of Wee1 in phosphorylating Tyr-15 in CDK1, fission yeast cells carrying a CDK1 mutation in which the tyrosine-15 residue is replaced by phenylalanine (which is structurally similar to tyrosine but cannot be phosphorylated) show the same premature mitotic CDK activation and entry into mitosis. In contrast, fission yeast cells carrying mutations in the *cdc25* gene arrest in G_2, giving rise to very long cells. This indicates that this phosphatase, which opposes Wee1 activity, is essential for entry into mitosis.

Vertebrates contain the same Wee1 protein kinase as *S. pombe* but have multiple Cdc25 phosphatases. Two family members, Cdc25B and Cdc25C, remove the inhibitory phosphorylation on CDK1 during G_2. Cdc25B is thought to act as a *starter* phosphatase that initiates

CDK1 activation, while Cdc25C is the *workhorse* phosphatase that activates the vast majority of cyclin-CDK1 complexes.

Abrupt activation of mitotic CDKs at the G_2/M transition is the consequence of rapid inactivation of Wee1 together with activation of Cdc25. Central to this rapid transition are two positive feedback loops built from CDKs, Polo-like kinase 1 (Plk1), and phosphoserine/threonine-binding domains, in which mitotic CDKs and Plk1 simultaneously activate Cdc25 and inactivate Wee1 (Figure 19-21). The process begins with Cdc25B, the starter phosphatase, activating an initial small pool of cyclin B-CDK1 at the centrosome (Figure 19-21, step **1**), which is thought to facilitate centrosome maturation. This initial pool of active cyclin B-CDK1 that is generated then phosphorylates Cdc25C, the workhorse phosphatase, in the cytoplasm. This recruits Pin1 and Plk1, which recognize Cdc25C through their phospho-binding domains. These proteins further modify and phosphorylate Cdc25C to stimulate its phosphatase activity (Figure 19-21, step **2**). This pool of active Cdc25C that is created, in turn activates the large pool of cytosolic cyclin B-CDK1, which activates more cytosolic Cdc25C as part of positive feedback loop 1. At the same time that Cdc25C is being activated, mitotic CDKs and Plk1 phosphorylate Wee1, which targets it for destruction through a phospho-binding SCF protein-ubiquitin ligase. This forms positive feedback loop 2 (Figure 19-21, step **3**). This combination of two positive feedback loops — one that activates a CDK1 activator (Cdc25C), and one that inhibits a CDK1

inhibitor (Wee1) — results in the abrupt and irreversible transition from G_2 into mitosis.

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

FIGURE 19-21 Positive feedback loops involving CDKs, Plk1, and phospho-binding domains result in abrupt mitotic CDK activation and the transition from G_2 into M phase. Although mitotic cyclins are synthesized during late S phase and G_2 and bind to CDK1, the cyclin-CDK complex is not active because threonine 14 and tyrosine 15 of the CDK1 subunit are phosphorylated by the protein kinase Wee1 (shown as red kinases), while the activating protein phosphatase, Cdc25, is phosphorylated and bound and inhibited by the phosphoserine/threonine-binding protein 14-3-3. The entire process of mitotic cyclin-CDK activation and entry into mitosis involves two positive feedback loops and coordination between events at the centrosome, in the cytoplasm, and in the nucleus. Step 1: At the centrosome, an initial pool of cyclin B-CDK1 is activated by Cdc25B, which removes the

inhibitory phosphorylations on threonine 14 and 15. This initial pool of active cyclin B-CDK1 then phosphorylates 14-3-3-bound Cdc25C on multiple serine-proline or threonine-proline sequences in the cytoplasm (shown as blue circles). Step **2**: The resulting phosphoserine/phosphothreonine-proline motifs created by cyclin B-CDK target Cdc25 for recognition by specific phospho-binding domains within the proline isomerase Pin1 and the protein kinase Plk1, which then bind to and further activate Cdc25C. Pin1 changes the conformation of Cdc25C while Plk1 catalyzes additional activating phosphorylations (shown as black circles). This releases Cdc25C from 14-3-3, allowing it to further de-phosphorylate and activate the larger cytosolic pool of cyclin B-CDK1. The resulting cyclin B-CDK1 drives further release and activation of more 14-3-3-bound Cdc25C, forming positive feedback loop 1. Step **3**: At the same time, the active cyclin B-CDK1 in the cytosol phosphorylates its inhibitory kinase Wee1 on serine-proline motifs, targeting it for recognition by the phospho-binding domain in Plk1. Plk1 then phosphorylates Wee1 on a motif that is recognized by the phospho-binding domain in the SCF-βTrCP ubiquitin protein ligase, targeting Wee1 for ubiquitination and destruction by the proteasome. This loss of Wee1 inhibition further enhances cyclin B-CDK1 activation, forming positive feedback loop 2. Step **4**: Active cytoplasmic cyclin B-CDK1 translocates into the nucleus, where it phosphorylates nuclear lamins to cause nuclear envelope breakdown and, together with Plk1 and the Aurora kinases, induces chromosome condensation and formation of the mitotic spindle.

Once the precipitous activation of mitotic CDKs is initiated, these protein kinases set in motion all the events necessary to ready the cell for chromosome segregation. The initial activation of mitotic CDKs at the centrosome, followed by activation in the cytoplasm, results in changes in the subcellular localization of these kinases. They enter the nucleus, where they bring about chromosome condensation and nuclear envelope breakdown (Figure 19-21, step **4**). In what follows, we discuss how the mitotic CDKs accomplish the coordinated execution of mitosis.

Just as S phase CDKs work together with DDK to promote MCM helicase activation during DNA replication initiation (see Section 19.4), mitotic CDKs collaborate in a similar manner with other protein kinases to bring about the mitotic events. Plk1 is critical for formation of the mitotic spindle as well as for chromosome segregation. The **Aurora kinase** family members Aurora A and Aurora B play key roles in mitotic spindle formation and in ensuring that chromosomes attach correctly to the mitotic spindle so that they are segregated accurately during mitosis. Their contributions to the various mitotic events will also be discussed.

Mitotic CDKs Promote Nuclear Envelope Breakdown

During interphase, chromosomes are surrounded by the nuclear envelope, while the centrosomes that nucleate the mitotic spindle are located in the cytoplasm. For nuclear chromosomes to interact with the cytoplasmic microtubules nucleated by the centrosomes, the nuclear envelope must be dismantled.

The nuclear envelope is a double-membrane extension of the endoplasmic reticulum containing many nuclear pore complexes (Figure 19-22a; see also Figures 1-12, 1-15, 13-33, and 18-52). The lipid bilayer of the inner nuclear membrane is associated with the nuclear lamina, a meshwork of lamin filaments adjacent to the

inside face of the nuclear envelope (Figure 19-22b) that participate in maintenance of nuclear structure and chromosome positioning within the nucleus (Figure 19-22c; see also Figure 1-15). The three nuclear lamins (A, B, and C) present in vertebrate cells belong to a class of cytoskeletal proteins, the intermediate filaments, that are critical in supporting cellular membranes. Once mitotic CDKs are activated at the end of G_2, they phosphorylate specific serine residues in all three nuclear lamins. This phosphorylation, together with phosphorylation of lamin B by protein kinase C, causes depolymerization of the lamin intermediate filaments (Figure 19-22d). Depolymerization of the nuclear lamins leads to disintegration of the nuclear lamina and contributes to disassembly of the nuclear envelope (Figure 19-22e).

FIGURE 19-22 Dissolution of the nuclear envelope during mitosis. (a) The nuclear lamins form a meshwork between the inner nuclear membrane and the underlying chromatin (see Figure 18-53). (b) Electron micrograph of the nuclear lamina from a *Xenopus* oocyte. (c) The nuclear lamin meshwork helps tether chromatin to nuclear pore complexes and to specific proteins in the nuclear membrane. (d) Phosphorylation of lamins adjacent to the head domains by cyclin B-CDK1 and protein kinase C, results in lamin disassembly and dissolution of the nuclear membrane into vesicles or retraction into the endoplasmic

reticulum. Phosphorylation of lamins A and C results in their solubilization and dispersal in the cytoplasm, while phosphorylation of lamin B dissociates it into membrane-bound subunits. (e) Human cells in which lamin A has been fused with GFP. The DNA has been stained blue with DAPI. The nuclear lamins are beginning to dissolve in early prometaphase. By metaphase, all of the lamin A fibers have been solubilized in the cytoplasm. (f) An overview of nuclear envelope breakdown during mitosis including disassembly of nuclear lamins and dispersal of the nuclear membrane.

Mitotic CDKs also affect other nuclear envelope components. The CDKs phosphorylate specific **nucleoporins**, which causes nuclear pore complexes to dissociate during prophase. Phosphorylation of integral membrane proteins of the inner nuclear membrane is thought to decrease their affinity for chromatin and further contributes to the disassembly of the nuclear envelope. Weakening of the associations between the inner nuclear membrane proteins and the nuclear lamina and chromatin allows sheets of inner nuclear membrane to retract into the endoplasmic reticulum, which is continuous with the outer nuclear membrane (Figure 19-22f).

Centrosomes Duplicate During S phase and Separate During Mitosis

A key function of mitotic CDKs, together with other protein kinases and ubiquitin-protein ligases, is to induce the formation of the **mitotic spindle**, also known as the *mitotic apparatus*. The function of the mitotic spindle is to segregate chromosomes so that the sister chromatids separate from each other and are moved to opposite poles of the cell (see Figure 18-39). In what follows, we describe how the mitotic spindle forms, how chromosomes attach to it, and how cells correct faulty attachments.

As we saw in Chapter 18, the mitotic spindle is made of microtubules that attach to chromosomes via specialized protein structures known as **kinetochores**, which form at the central centromeric region of chromosomes. In most organisms, the mitotic spindle is built between two **centrosomes** (called **spindle pole bodies** in yeast), that lie at opposite ends (poles) of the spindle (Figure 19-23; also see Figure 18-39). Centrosomes contain a specialized type of tubulin, γ tubulin, which forms specific ringlike complexes (γ TuRCs) that, together with a variety of associated proteins, have the ability to nucleate microtubules and form a bipolar spindle. [Notable exceptions to these centrosome-based spindle assembly mechanisms are seen in higher plants and metazoan oocytes. In these cells, the (−) ends of microtubules are cross-linked, and the microtubules self-assemble into a spindle.] In either case, the ends of the mitotic spindle are always referred to as *spindle poles*, and in animal cells these typically arise from centrosomes.

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

FIGURE 19-23 The centrosome cycle is coordinated with the cell cycle to form a bipolar spindle that can correctly segregate chromosomes in mitosis. (a) Thin section electron

micrograph of an interphase centrosome showing two centrioles at right angles to each other surrounded by pericentriolar material. (b) Diagram of the centrosome showing each centriole composed of nine triplet outer microtubules embedded in pericentriolar material that contains γ-TuRC nucleating structures. The original mother centriole from the prior cell division is marked with additional appendages shown as blue spheres, and the centrioles are connected by a flexible protein linker. (c) Stages of the centrosome cycle. Step **1**: G_1/S CDKs and Plk4 induce each centriole (green) to produce a daughter procentriole, which elongates during S phase. Step **2**: The kinase Nek2 drives cleavage of the protein linker connecting the two original centrioles, while CDK1, Plk1, and Aurora A induce accumulation of large amounts of PCM (blue). Step **3**: Each centriole-procentriole pair together with its associated PCM separates from the other, forming two individual, mature centrosomes located on opposite sides of the cell nucleus. The mitotic spindle that forms between them segregates the chromosomes during the next steps in mitosis. Step **4**: At the end of mitosis, Plk1, together with a protease called *separase*, promotes centriolar disengagement, separating the former centriole-procentriole pair from the orthogonal arrangement they had during mitosis. This Plk1-mediated separation so to speak licenses the centrosome, so that procentriolar formation and centrosome duplication can only happen once each cell cycle. This is conceptually similar to how CDK activity licenses replication origins (see Figure 19-19) so that they can only fire once each cell cycle.

Cell Biol*. **6**:743–748; permission conveyed through Copyright Clearance Center, Inc. Part (c) Data from P. T. Conduit, A. Wainman, and J. W. Raff, 2015, *Nat. Rev. Mol. Cell Biol.* **16**:611–624.]

During G_1, cells contain a single centrosome, which functions as the major microtubule nucleating center of the cell. In order for this single centrosome to create a mitotic spindle, it has to duplicate into two centrosomes and acquire additional proteins and modifications through a process called *centrosome maturation*. The two centrosomes then have to move to opposite sides of the cell and nucleate a mitotic spindle. Once mitosis is completed, the

centrosome must re-form its G_1-like structure. This sequence of events is sometimes called the *centrosome cycle* (Figure 19-23c), which is tightly coordinated with the cell cycle overall.

Mitotic spindle formation actually begins at the G_1–S phase transition with the duplication of the centrosome. How duplication occurs is not completely understood, but at the heart of this process is duplication of the pair of **centrioles**, short, microtubule-based structures arranged orthogonally to each other and surrounded by proteinaceous pericentriolar material (PCM). As discussed in Chapter 18, G_1 cells contain a single pair of centrioles, which are connected together by a flexible protein linker (Figure 19-23a and b). As a cell enters S phase, each of the two centrioles begins to duplicate by growing a new daughter procentriole (Figure 19-23c). This process is initiated by the G_1/S cyclin-CDKs and is largely controlled by a member of the Polo-like kinase family, Plk4, which phosphorylates additional centriole-associated proteins. They recruit γ-tubulin complexes that help form the new procentrioles (Figure 19-23c, step **1**). The procentrioles enlarge during S phase so that by G_2 each centriole has made an exact copy of itself. The two centriole-procentriole pairs remain in close proximity to each other. At the G_2/M transition, the protein linker connecting the two original centrioles is dissolved (Figure 19-23c, step **2**). This process, called **centrosome disjunction**, creates two separate centrosomes. Each centrosome expands its complement of pericentriolar material. The centrosomes recruit more γ TuRCs,

allowing the centrosome to efficiently organize and nucleate the large number of microtubules that are required for mitotic spindle formation and function (Figure 19-23c, step **3**). Once the cell enters prophase, the mature centrosomes separate from one another and move to opposite sides of the cell nucleus, where they create the mitotic spindle. This occurs in close proximity to the still-intact nuclear envelope through the actions of a kinesin motor protein (see Chapter 18), which pushes apart overlapping microtubules emanating from each centrosome. The specifics of microtubule formation, mitotic spindle assembly, and microtubule motors were discussed in Chapter 18. Here we briefly consider how chromosomes attach to the mitotic spindle and how mistakes in the process are corrected.

Mitotic CDKs, Polo-like Kinases, and Aurora Kinases Drive Assembly of a Mitotic Spindle That Attaches to the Kinetochores of Condensed Chromosomes

For chromosomes to be accurately segregated during mitosis, they must attach to the mitotic spindle in such a way that one kinetochore of each sister chromatid pair attaches to microtubules emanating from opposite spindle poles. Once this happens, the

sister chromatids are said to be **bi-oriented** (Figure 19-24a). This type of attachment, in which the kinetochores of each sister chromatid are attached to microtubules coming from opposing centrosomes, is called an **amphitelic attachment**. How is this accomplished? Once centrosomes have moved apart from each other during prophase, and the nuclear envelope has broken down during prometaphase (see Figure 19-3), microtubules, in a search-and-capture mechanism, begin to interact with the kinetochores of sister chromatid pairs. Initially, chromosomes glide along the length of microtubules, propelled by motor proteins. When a chromosome reaches the (+) end of a microtubule, the kinetochores attach to microtubules in an end-on attachment, the final configuration in which chromosomes are linked to the mitotic spindle (Figure 19-24b and c; also see Figure 18-42). Kinetochores of sister chromatids then bind microtubules emanating from the opposite spindle poles, allowing the chromosomes to separate by poleward pulling forces coming from motor proteins at the kinetochore.

(b)

(c)

FIGURE 19-24 Chromosome attachment to the mitotic spindle. (a) Chromosomes attach to the mitotic spindle and accumulate at the spindle center. They then attach, via their kinetochores, to the ends of microtubules (called *end-on attachments*), and these attachments are stabilized by additional microtubules. The final chromosome attachment, in which the chromosome is stably bi-oriented on the mitotic spindle, is shown. "(–)" indicates the minus end of the microtubule, "(+)" the plus end. The boxed region at the kinetochore is explained in parts b and c. (b) Electron micrograph of a microtubule bound end-on to a purified yeast kinetochore. (c) Schematic cartoon illustrating the key features shown in part (b) and the boxed area in part (a). The ring structure embracing the microtubule most likely represents

the outer kinetochore Dam1 complex (called the *Ska complex* in metazoans) and part of the Ndc80 complex, also an outer kinetochore component. The globular structure at the end of the complex most likely reflects the inner kinetochore and protein complexes that link the inner kinetochore to the outer kinetochore.

[Part (b) Reprinted with permission from Nature Publishing Group, from S. Gonen et al., 2012, *Nat. Struct. Mol. Biol*. **19**:925–929, Fig. 2d; permission conveyed through Copyright Clearance Center, Inc. Part (c) Information from S. Gonen et al., 2012, *Nat. Struc. Mol. Biol.* **19**:925–929, Fig. 1a.]

Before the chromosomes can be separated by poleward pulling forces, each and every chromosome in the cell has to be properly attached to the mitotic spindle in a bi-oriented amphitelic attachment (Figure 19-25a). How does the cell know that this has occurred? Microscopic analysis of chromosome attachment has shown that, initially, many chromosomes attach to microtubules in faulty ways. A kinetochore can attach to microtubules emanating from both poles at the same time, a situation called **merotelic attachment** (Figure 19-25b). Alternatively, both kinetochores of a sister chromatid pair can attach to microtubules from the same pole (**syntelic attachment**; Figure 19-25c), or only one kinetochore can attach to microtubules (**monotelic attachment**; Figure 19-25d). Clearly none of these attachments would result in accurate chromosome segregation, since the sister chromatids would not be pulled apart to opposite spindle poles. Thus mechanisms must be in place that detect and correct such faulty kinetochore-microtubule attachments.

FIGURE 19-25 Stable and unstable chromosome attachments. When sister kinetochores attach to microtubules emanating from opposite spindle poles, they are stably attached. This configuration is called *amphitelic attachment* (a). Microtubules (green) pull kinetochores; cohesins resist this pulling force. The resulting tension leads to the outer kinetochore component Ndc80 (orange) being pulled away from the protein kinase Aurora B (colored red), which localizes to the inner kinetochore when chromosomes are near the spindle midzone. As a result, Aurora B can no longer phosphorylate Ndc80, and kinetochore-microtubule attachments are stable. When one of the two sister chromatid kinetochores simultaneously attaches to microtubules emanating from two opposite spindle poles [merotelic attachment, (b)], or both sister kinetochores attach to microtubules emanating from the same spindle pole [syntelic attachment, (c)], or only one of the two sister kinetochores attaches to microtubules [monotelic attachment, (d)], Ndc80 is not pulled away from Aurora B. As a result, Aurora B phosphorylates Ndc80 (yellow circles labeled 'P'), and Ndc80 can no longer form stable attachments to microtubules.

The sensing mechanism used by cells to detect incorrect chromosome attachments is based on tension. When sister chromatids are correctly attached to microtubules, their kinetochores are under tension (Figure 19-25a). Microtubules attached to the kinetochores pull at them, while the cohesin molecules that hold the sister chromatids together withstand these forces, creating tension at the kinetochores. Merotelic, syntelic, or monotelic attachment leads to insufficient tension at kinetochores, allowing the cell to distinguish these faulty forms of attachment from the correct amphitelic one.

How does the cell measure whether or not kinetochores are under tension? The Aurora protein kinase family members *Aurora A* and *Aurora B* and their associated regulatory factors sense kinetochores that are not under tension and sever these microtubule attachments, giving cells a second chance to get the attachment right. The molecular basis for this sensing mechanism is reasonably well understood. Recall that outer kinetochore components, especially the Ndc80 complex, bind to microtubules (see Figure 19-24c) in a manner that is stabilized by the Ska complex (or the Dam1 complex in yeast). Aurora kinases phosphorylate the N-terminal tail of Ndc80. When phosphorylated, Ndc80 loses its ability to form stable interactions with microtubules. Aurora B localizes to the inner kinetochore and is thought to be the dominant error-correcting kinase for chromosomes along most of the spindle. When kinetochores are not under tension, Ndc80 is in close proximity to

Aurora B, and the protein kinase can phosphorylate the protein, destabilizing any kinetochore-microtubule attachments (Figure 19-25b–d). When microtubules are attached correctly to kinetochores, microtubule forces pull Ndc80 away from Aurora B, and the kinase can no longer phosphorylate Ndc80 (Figure 19-25a). Protein phosphatase 1 (PP1) localizes to the outer kinetochore and continuously de-phosphorylates Ndc80. Thus, when kinetochores are under tension and pulled away from Aurora B, Ndc80 is quickly de-phosphorylated by PP1 and microtubule–kinetochore attachments are stabilized. A similar mechanism is thought to operate on kinetochore-microtubule interactions close to the spindle poles, where Aurora A substitutes for Aurora B.

Microtubules continuously pull on chromosomes. Once all the chromosomes have attached to microtubules in an amphitelic manner, only the cohesins that hold them back in the middle of the spindle (Figure 19-25a) prevent chromosomes from segregating to the poles. As we will see in Section 19.6, it is the severing of these cohesins that initiates anaphase chromosome segregation and drives mitotic exit. Again, just as in S phase entry, mitotic entry, chromosome replication, and the centrosome cycle, protein phosphorylation and de-phosphorylation by protein kinases and phosphatases control all of the events leading to chromosome separation.

Chromosome Condensation Facilitates Chromosome Segregation

Chromosome segregation not only requires building the apparatus that segregates chromosomes, but it also requires that the DNA be compacted into travel-friendly structures. Any attempt to segregate the long and intertwined DNA-protein complexes present in interphase cells would lead to DNA breakage and loss of genetic material. To avoid this fate, cells compact their chromosomes during prophase into the dense structures we have become acquainted with through light and electron microscopy (Figure 19-26a and see Figure 19-2).

FIGURE 19-26 The Condensin complex packages chromosomes for efficient segregation on the mitotic spindle. (a) Electron micrograph of a metaphase chromosome. By metaphase, the chromosomes are fully condensed, and the two individual sister chromatids are visible. (b) The condensin complexes have a similar architecture to the cohesin complex discussed previously. (c) A model of cell cycle regulated chromosome compaction involving progressive chromosome looping. During prophase, prior to nuclear envelope breakdown, condensin II binds DNA and extrudes large loops. After nuclear envelope breakdown in prometaphase, condensin I forms additional loops nested within the loops formed by condensin II.

Chromosome condensation results in a dramatic reduction in chromosome length, up to 10,000-fold in vertebrates. During chromosome compaction, the intertwined sister chromatids are also untangled. This process, called **sister chromatid resolution**, is mediated in part by topoisomerase II, which cuts one chromatid in a pair of sister chromatid molecules, passes the other one through, and closes the cut molecule. As part of this process, during prophase most of the cohesin proteins that tether sister chromatids together along the chromosome arms are shed through the actions of Plk1 and Aurora B.

Central to the process of chromosome condensation is another ring-shaped protein complex known as **condensin**. Most eukaryotes have two closely related condensin complexes, called *condensin I* and *II*. These protein complexes are closely related to the cohesins that link sister chromatids together (Figure 19-26b). Condensins were first identified based on their ability to promote chromosome condensation in frog egg extracts. Like cohesins, condensins are composed of two large coiled-coil SMC protein subunits that associate through their ATPase domains with non-SMC subunits. When condensin function is lost in cells, chromosomes do not condense and sister chromatid tangles are not resolved.

Recent studies have shown that chromosome compaction occurs via the generation of consecutive loops that lead to the formation of a fiber at the bases of the loops (Figure 19-26c). These fibers are

compressed, leading to further chromosome compaction. Condensins likely package chromosomes by creating these loops by forming intrachromosomal linkages, through the process explained in Figure 19-26c. Condensin association with chromosomes is facilitated by mitotic CDKs and Aurora B, which phosphorylate histone H2A (see Figure 7-26b), allowing condensins to bind chromatin.

KEY CONCEPTS OF SECTION 19.5

The G_2/M Transition and the Irreversible Engine of Mitosis

- Mitotic CDKs induce entry into mitosis in all eukaryotes.
- Mitotic CDKs are kept inactive by inhibitory phosphorylation of the CDK subunit until the completion of DNA replication (see Figure 19-21).
- Mitotic CDKs promote their own activation through two positive feedback loops that inactivate Wee1 kinase and activate Cdc25 phosphatase (see Figure 19-21).
- Mitotic CDKs induce nuclear envelope breakdown in most eukaryotes by phosphorylating lamins (see Figure 19-22).
- Centrosome duplication occurs during S phase. Mitotic CDKs induce the separation of the duplicated centrosomes, which initiates mitotic spindle formation (see Figure 19-23).
- Sister chromatids attach to the mitotic spindle via their kinetochores in a bi-oriented manner, with one sister kinetochore attaching to microtubules emanating from one spindle pole and the other one to microtubules nucleated by the other spindle pole (see Figure 19-24).
- Cells sense bi-orientation of sister chromatids through a tension-based mechanism. When kinetochores are not under tension, the protein kinases Aurora A and Aurora B phosphorylate the microtubule-binding subunits of the kinetochore, which limits their ability to form stable long-lasting interactions (see Figure 19-24).
- Chromosomes must be compacted for segregation to occur.
- Condensins, protein complexes that are related to cohesins, facilitate chromosome condensation and are activated by mitotic CDKs (see Figure 19-26).

19.6 The Mitotic Spindle, Chromosome Segregation, and Exit from Mitosis

Once all chromosomes have condensed and have correctly attached to the mitotic spindle, chromosome segregation commences. In this section, we discuss how cleavage of cohesins by a protease known as *separase* triggers anaphase chromosome movement and how this cleavage is regulated by phosphorylation and protein ubiquitination. We then see how the same machinery that initiates cohesin cleavage at the metaphase-anaphase transition also initiates mitotic CDK inactivation. Next we describe how phosphatases activated at the end of mitosis also participate in mitotic CDK inactivation, bringing about the disassembly of mitotic structures and the resetting of the cell to the G_1 state. We end this section with a discussion of cytokinesis, the process that produces two daughter cells.

Separase-Mediated Cleavage of Cohesins Initiates Chromosome Segregation

As mentioned in the previous section, chromosome condensation and dissociation of cohesins along the chromosome arms leads to further compaction of chromosomes. Most of the cohesins along the

chromosome arms are removed from chromosomes during prophase (Figure 19-27a, steps **1** and **2**). This process is mediated by phosphorylation of cohesins by Plk1 and Aurora B kinase. In most organisms, by metaphase, cohesins are maintained only around centromeres. These centromere-associated cohesins are specifically protected from phosphorylation-dependent removal by protein phosphatase 2A (PP2A). This phosphatase is recruited to centromeric regions in human cells from G_2 through metaphase by a member of a family of PP2A targeting factors known as the *Shugoshin* family of proteins (Figure 19-27b). The protected pool of cohesins provides the resistance to the pulling force exerted by microtubules that are necessary to establish tension at bi-oriented kinetochores. As we will see in Section 19.8, this protection mechanism also plays an essential role in establishing the meiotic chromosome segregation pattern.

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

FIGURE 19-27 Cleavage of cohesin at centromeres by separase triggers anaphase onset. (a) A multistep process removes the cohesin that links sister chromatids. Step **1**: During G_2, when sister chromatids are linked along their entire length by cohesins, the Shugoshin proteins begin recruiting the protein phosphatase 2A (PP2A) to centromeric regions. This recruitment process continues through the beginning of prophase when CDK1 triggers chromosome condensation. Step **2**: Later in prophase and early metaphase, cohesin along the chromosome arms is shed by the action of a protein complex in combination with phosphorylation of cohesins by Polo kinase and Aurora B kinase. However, cohesin remains tightly associated with centromeric regions of the chromosome because PP2A localized there removes any phosphates added by the Plk1 kinase. Finally, in step **3** separase cleaves the residual centromeric cohesin, triggering the onset of anaphase, releasing the sister chromatids, which move rapidly toward opposite spindle poles. (b) Diagrammatic representation of Shugoshin-PP2A recruitment and retention at centromeric chromatin.

Each sister chromatid of a metaphase chromosome is attached to microtubules via its kinetochore (see Figure 19-24). Once all of the chromosomes have made stable amphitelic attachments to the spindle pole microtubules and congressed to the spindle midzone at metaphase, the chromosomes will be in a state of tension, with forces pulling the two kinetochores toward opposite spindle poles. Sister chromatids do not separate from each other yet, however, because they are held together at their centromeres by what remains of the cohesion attachments. In all organisms analyzed to date, the loss of this residual cohesin from the centromeric regions of chromosomes is what triggers anaphase chromosome movement (Figure 19-27a, step **3**). The mechanism that brings about this loss of cohesins from chromosomes is conserved as well. A protease known as **separase** cleaves the cohesin subunit Scc1 (Figure 19-28), breaking the protein circles linking sister chromatids. Once this link

is broken, anaphase begins as poleward force exerted on the kinetochores moves the split sister chromatids toward opposite spindle poles.

FIGURE 19-28 Regulation of separase through phosphorylation and ubiquitin-mediated degradation of an inhibitor establishes the timing of cohesin cleavage. Separase is inhibited before anaphase by the binding of the protein securin. Mitotic CDKs also inhibit separase by phosphorylating it. When all the kinetochores have properly attached to spindle microtubules and the spindle apparatus is properly assembled and oriented, the Cdc20 specificity factor associated with APC/C directs it to ubiquitinylate securin and mitotic cyclins. Following securin degradation and a decrease in mitotic CDK activity, separase cleaves the Scc1 subunit, breaking the cohesin circles and allowing sister chromatids to be pulled apart by the spindle apparatus that is pulling them toward opposite spindle poles.

Cohesin cleavage was discovered in budding yeast. Insight into the identity of the protein that was responsible for the cleavage of cohesin came from analysis of previously identified yeast mutants that failed to segregate chromosomes during anaphase. A mutant form of the gene encoding Esp1 — what we now call separase — failed to produce the cleavage fragment. Subsequent analyses revealed that separase is a protease and that cleavage of cohesin by separase is essential for chromosome segregation. Given the

irreversible nature of Scc1 cleavage, it is absolutely essential that separase activity be tightly controlled. Next we discuss its regulation.

APC/C Activates Separase Through Securin Ubiquitinylation

Prior to anaphase, the protein **securin** binds to and inhibits separase (see Figure 19-28). Once all kinetochores have attached to spindle microtubules in the correct bi-oriented manner, the APC/C ubiquitin-protein ligase, directed by specificity factor Cdc20 (known as APC/C^{Cdc20}) (see Figure 19-14), ubiquitinylates securin. The polyubiquitinylated securin is rapidly degraded by proteasomes, thus releasing separase.

$\mathrm{APC/C^{Cdc20}}$ is phosphorylated and activated in prophase by mitotic CDK phosphorylation. We will see in Section 19.7, however, that phosphorylated $\mathrm{APC/C^{Cdc20}}$ is inhibited by a checkpoint pathway — the spindle assembly checkpoint pathway — that ensures anaphase is not initiated until all of the chromosomes have achieved proper attachment to the mitotic apparatus (i.e., are bi-oriented). Cdc20 is inhibited until every kinetochore has attached to microtubules and proper tension has been applied to the kinetochores of all sister chromatids. In vertebrate cells, separase itself is also negatively regulated by CDK phosphorylation during prophase and metaphase.

Separase becomes active and triggers chromosome segregation when APC/C^{Cdc20}-mediated protein degrades because mitotic CDK activity begins to decline at the metaphase-anaphase transition.

Once cohesins are cleaved, anaphase chromosome movement ensues. As discussed in Chapter 18, chromosome segregation is mediated by microtubule depolymerization and motor proteins as the spindle poles move away from each other. Decline in mitotic CDK activity is important for these anaphase chromosome movements. If mitotic CDK inactivation is inhibited, anaphase does occur, but it is abnormal. De-phosphorylation of a number of microtubule-associated proteins that affect microtubule dynamics appears to be important for this process. In budding yeast, this de-phosphorylation is brought about by the protein phosphatase Cdc14, which, as we will see, plays an essential role in the final cell cycle stage, exit from mitosis.

Mitotic CDK Inactivation and Protein De-phosphorylation Triggers Exit from Mitosis

Anaphase spindle elongation and the events associated with exit from mitosis — mitotic spindle disassembly, chromosome decondensation, and nuclear envelope re-formation — require the de-phosphorylation of CDK substrates. In other words, the

phosphorylation events that triggered all of the different mitotic events need to be undone for the cell to revert to the G_1 state.

De-phosphorylation of mitotic CDK substrates involves two steps. First, the mitotic CDKs themselves have to be inactivated. In most organisms, mitotic CDK inactivation is triggered by APC/C^{Cdc20}-mediated degradation of mitotic cyclins. However, in budding yeast, only about 50 percent of mitotic cyclins are degraded by APC/C^{Cdc20}. An additional pathway called the *mitotic exit network* plays a particularly important role in shutting off mitotic cyclins in yeast by controlling the activation of the **Cdc14 phosphatase** through a GTPase pathway called the mitotic exit network. Activation of Cdc14 at anaphase de-phosphorylates Cdh1, allowing formation APC/C^{Cdh1}, which then degrades the remaining mitotic cyclins. In addition, Cdc14 promotes the re-accumulation of the CDK inhibitor Sic1, which inhibits any residual mitotic CDK activity, similarly to how it inhibits G_1/S phase cyclins in previous stages of the cell cycle (Section 19-4). This process leads to exit from mitosis. Phosphatase activity is also essential for exit from mitosis in vertebrate cells, although they do not appear to possess a mitotic exit network like that found in budding yeast.

Ultimately, reversal of mitotic CDK phosphorylation changes the activities of many proteins back to their interphase states. De-phosphorylation of condensins and other chromatin-associated proteins leads to decondensation of mitotic chromosomes in

telophase. De-phosphorylated inner nuclear membrane proteins are thought to bind to chromatin once again. As a result, multiple projections of regions of the ER membrane containing these proteins are thought to associate with the surfaces of the decondensing chromosomes and then fuse with one another, directed by an unknown mechanism to form a continuous double membrane around each chromosome (Figure 19-29). De-phosphorylation of nuclear pore subcomplexes allows them to reassemble into complete NPCs traversing the inner and outer membranes soon after fusion of the ER projections. Ran·GTP, required for driving most nuclear import and export (see Chapter 13), stimulates both fusion of the ER projections to form daughter nuclear envelopes and assembly of NPCs (Figure 19-29). The Ran·GTP concentration is highest in the vicinity of the decondensing chromosomes because the Ran-guanine nucleotide–exchange factor (Ran-GEF) is bound to chromatin. Consequently, membrane fusion is stimulated at the surfaces of decondensing chromosomes. Sheets of nuclear membrane with inserted NPCs then fuse with one another to form one nuclear membrane around all of the chromosomes.

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

FIGURE 19-29 Model for reassembly of the nuclear envelope during telophase. Extensions of the endoplasmic reticulum (ER) associate with each decondensing chromosome and then fuse with one another, forming a double membrane around the chromosome. De-phosphorylated nuclear pore subcomplexes reassemble into nuclear pores, forming individual mini-nuclei called *karyomeres*. The enclosed chromosome further decondenses, and subsequent fusion of the nuclear envelopes of all the karyomeres at each spindle pole forms a single nucleus containing a full set of chromosomes. NPC: nuclear pore complex. See B. Burke and J. Ellenberg, 2002, *Nat. Rev. Mol. Cell Biol.* **3**:487–497.

Cytokinesis Creates Two Daughter Cells

When chromosome segregation is completed, the cytoplasm and organelles are distributed between the two future daughter cells. This process is called **cytokinesis**. With the exception of higher plants, the division of the cell is brought about by a contractile ring made of actin and the actin motor myosin (see Figure 17-34). During cytokinesis, the ring contracts in a manner similar to muscle contraction, pulling the membrane inward and eventually closing the connection between the two daughter cells (Figure 19-30).

FIGURE 19-30 Control of RhoA regulates cytokinesis. (a) The Centralspindlin complex (green) recruits and activates the RhoGEF Ect2 (orange) at the central spindle during anaphase. These colocalize with and activate RhoA (red) on the cell cortex opposite the central spindle, generating an actomyosin-based contractile ring that creates a cleavage furrow and divides the cell in half. (b) Molecular pathway of RhoA activation and control of cleavage furrow formation by phosphorylation.

[Information from A. Basant and M. Glotzer, 2018. *Curr. Biol*. **28**:R570-R580.]

Cytokinesis must be coordinated with other cell cycle events in space and time. For cell division to produce two daughter cells each containing half of the parent cell's cytoplasmic content and exactly half of the genetic content, the division plane must be properly spatially positioned. Cytokinesis must also be temporally

coordinated with completion of mitosis. In what follows, we explore both these aspects of cytokinesis regulation.

In animal cells, the contractile ring forms during anaphase and must be placed exactly in the middle of the anaphase spindle to ensure that each daughter cell receives half of the genetic material. Contractile ring assembly requires the small GTPase RhoA (see Section 17.7). Regions of active RhoA form on the cortical surface of the cell opposite the central part of the spindle at sites where the contractile ring will form (Figure 19-30a). Active GTP-bound RhoA both stimulates formin-mediated F-actin assembly and promotes the action of myosin II (see Figure 17-42). Recall that in yeast, small GTPases play a critical role in forming the mitotic exit network, which is absent in animal cells. Instead, small GTPases in animal cells are required for cytokinesis through a process that is tightly controlled by mitotic protein kinases (Figure 19-30b).

RhoA itself is activated by a conserved Rho guanine nucleotide–exchange factor (GEF) called *Ect2*, which is itself tightly regulated by a multiprotein complex called *Centralspindlin*. Centralspindlin is a heterotetramer composed of two copies of the kinesin-6 motor protein MKLP1 and a dimer of a Rho GTPase-activating protein (GAP). As one can guess from its name, most of the Centralspindlin localizes to the midzone of the anaphase spindle, where the MKLP1 components form oligomers that bundle spindle microtubules and organize the central spindle in preparation for cell abscission at the

end of cytokinesis. A variable amount of Centralspindlin, however, localizes to the cell cortex adjacent to the central spindle, together with the RhoA activator Ect2 and RhoA (Figure 19-30a). MKLP1 is inhibited by the phosphoserine/threonine-binding protein 14-3-3 (see Figure 19-30b). This ensures that the spindle midzone microtubules do not compact until the end of anaphase. Similarly, the RhoA activator Ect2 is auto-inhibited during prior stages of mitosis, but it contains two phospho-binding BRCT domains that are important for its activation. During anaphase, when cyclin B–CDK1 activity is extinguished but Aurora and Polo kinases are still active, Aurora B phosphorylates MKLP1 and displaces the 14-3-3 inhibitor, allowing MKLP1 to acquire catalytic motor activity and compact the spindle midzone. At the same time, Plk1 phosphorylates the Rho-GAP component, recruiting the BRCT domains of Ect2 to form an active Centralspindlin-Ect2 complex. This catalyzes the GTP-dependent activation of RhoA, leading to cleavage furrow formation and division of the cytoplasm to form two completely separate cells.

This concludes our discussion of the molecular events of cell division. As we have seen, cyclin-dependent kinases, phosphoserine/threonine-binding domains, and ubiquitin-mediated protein degradation are at the center of its control (Figure 19-31). In Section 19.7, we discuss the mechanisms that ensure that a cell cycle stage is not initiated until the previous one has been completed and that each cell cycle step occurs accurately.

FIGURE 19-31 Fundamental processes in the eukaryotic cell cycle. A synopsis of major events that regulate progression through the cell cycle. See text for details.

KEY CONCEPTS OF SECTION 19.6

The Mitotic Spindle, Chromosome Segregation, and Exit from Mitosis

- Cleavage of cohesin by separase induces chromosome segregation during anaphase.
- At the onset of anaphase, APC/C is directed by Cdc20 to ubiquitinylate securin, which is subsequently degraded by proteasomes. The degradation of securin, along with phosphorylation by Plk1, activates separase (see Figure 19-28).
- Exit from mitosis is triggered by mitotic CDK inactivation mainly brought about by mitotic cyclin degradation.

- Exit from mitosis requires the activity of protein phosphatases such as Cdc14 to remove mitotic phosphates from many different proteins, permitting mitotic spindle disassembly, decondensation of chromosomes, and reassembly of the nuclear envelope.
- Cytokinesis finalizes cell fission and must be coordinated with the site of nuclear division. In animal cells, this coordination involves the small GTPase RhoA and is regulated by Plk1, Aurora B, and phospho-binding domains (see Figure 19-30).

19.7 Surveillance Mechanisms in Cell Cycle Regulation

Surveillance mechanisms known as **checkpoint pathways** operate to ensure that the next cell cycle event is not initiated until the previous one has been completed. Checkpoint pathways consist of **sensors** that monitor a particular cellular event, a **signaling cascade** that initiates the response, and an **effector** that halts cell cycle progression and activates repair pathways when necessary until the defect is corrected. If the defect cannot be repaired, the checkpoint pathway induces apoptosis.

Cell cycle events monitored by checkpoint pathways include growth, DNA replication, DNA damage, kinetochore attachment to the mitotic spindle, and positioning of the spindle within the cell. These pathways are responsible for the extraordinarily high fidelity of cell division, ensuring that each daughter cell receives the correct number of accurately replicated chromosomes. Checkpoint pathways function through protein phosphorylation, targeting proteins to bind to phosphoserine/threonine-binding domains that control the activities of the cyclin-CDKs. This control involves a variety of mechanisms: blocking synthesis and increasing degradation of cyclins, phosphorylating CDKs at inhibitory sites, sequestering CDK activators away from the CDKs, stabilizing CDK inhibitors (CKIs) that inactivate cyclin-CDK complexes, and inactivating the APC/C ubiquitin-protein ligase.

The DNA Damage Response System Halts Cell Cycle Progression and Recruits DNA Repair Machinery When DNA Is Compromised

The complete and accurate duplication of the genetic material is essential for cell division. If cells enter mitosis when DNA is incompletely replicated or otherwise damaged, genetic changes occur. In many instances, those changes lead to cell death, but as we will see in Chapter 25, they can also lead to genetic alterations that result in loss of control over cell growth and division and, eventually, cancer. This risk is underscored by the finding that many proteins involved in sensing DNA damage and its repair are frequently found mutated in human cancers.

The enzymes that replicate DNA are accurate, but not enough to ensure complete accuracy during DNA synthesis. Furthermore, environmental insults such as x-rays and UV light can cause DNA damage, and this damage must be repaired before a cell enters mitosis. Cells possess a *DNA damage response system* that senses many different types of DNA damage and responds by activating repair pathways and halting cell cycle progression until the damage has been repaired. Cell cycle arrest can occur in G_1, S phase, or G_2, depending on whether DNA damage occurred before cell cycle entry or during DNA replication. In multicellular organisms, when the

DNA damage is severe, cells forego repair and instead initiate either apoptosis ("programmed cell death"), a mechanism that is discussed in detail in Chapter 22, or they senesce, becoming large, flattened cells that have permanently stopped dividing.

DNA damage exists in many different forms and degrees of severity. A break of the DNA helix, known as a *double-strand break*, is perhaps the most severe form of damage because such a lesion would almost certainly lead to DNA loss if mitosis ensued in its presence. This is because the severed piece of DNA that was not attached to the centromere of the chromosome, where the kinetochore assembles, would not be reliably separated into the two daughter cells. More subtle defects include single-strand breaks, structural changes in nucleotides, and DNA mismatches. For our discussion here, it is important to note that cells have sensors for all these different types of damage. These sensors scan the genome and, when they detect a lesion, assemble signaling and repair factors at the site of the lesion.

Central to the detection of these different types of lesions is a pair of homologous protein kinases called **ATM** (for **ataxia telangiectasia mutated**) and **ATR** (for **ataxia telangiectasia and Rad3-related protein**). In addition to ATM and ATR, a related protein kinase called **DNA-PK** (for **DNA-dependent protein kinase**) is also critical for DNA damage signaling and repair. All three protein kinases are recruited to sites of DNA damage through specific protein complexes that form on the chromatin at the site of the damage. They then

initiate the sequential recruitment of adapter proteins and DNA repair proteins near the site of the DNA lesion. In addition, they activate another set of downstream effector protein kinases called *Chk1, Chk2*, and *MK2* that establish and maintain cell cycle checkpoints that stop progression through the cell cycle (Figure 19-32).

FIGURE 19-32 An overview of the DNA damage response system. The protein kinases DNA-PK, ATM, and ATR are activated at sites of damaged DNA. ATR responds to a variety of DNA damage — most likely to the single-stranded DNA that exists either as a result of the damage itself or as a result of repair. ATM and

DNA-PK are specifically activated by double-strand breaks. Because double-strand breaks are converted into single-stranded DNA as a part of the repair process, they also, albeit indirectly (as depicted by a dashed line), activate ATR. These kinases phosphorylate additional proteins at the DNA lesion resulting in the recruitment and activation of DNA repair machinery. ATM and ATR, once activated by DNA damage, activate a triad of related protein kinases, Chk1, Chk2, and MK2. These kinases cause cell cycle arrest by phosphorylating and thus inhibiting Cdc25 and also by stabilizing the transcription factor p53, which induces the transcription of the CDK inhibitor CKI p21. If the DNA damage is severe, p21 can cause the cells to senesce or p53 can induce apoptosis.

ATR, ATM, and DNA-PK recognize different types of DNA damage. ATM and DNA-PK respond primarily to double-strand breaks. ATR recognizes diverse types of DNA damage, such as stalled replication forks, DNA mismatches, damaged nucleotides, and single-strand breaks. ATR recognizes these diverse types of damage because all of them contain some amount of *single-stranded DNA*, either as part of the damage itself or because repair enzymes create single-stranded DNA as part of the repair process. ATR binding to single-stranded DNA is mediated through an ATR-interacting protein called *ATRIP* and results in increased ATR protein kinase activity. ATR then phosphorylates adapter proteins whose function is to recruit DNA repair proteins and help activate the Chk1 and MK2 kinases that stop progression through the cell cycle until the damage is repaired.

Both DNA-PK and ATM recognize double-strand DNA breaks. Two subunits of DNA-PK, called *Ku70/80*, form a ringlike structure that encircles the free DNA end. In contrast, ATM is directly recruited to

the DNA ends by a protein complex known as the *MRN complex* (Figure 19-33, step **1**). Binding of DNA-PK and ATM to the broken ends helps to hold them together. ATM also activates Chk2 and MK2 to stop progression through the cell cycle until repair is complete. In addition, DNA-PK, ATM, and ATR phosphorylate a variant histone called *H2AX* within the chromatin near the damage site (Figure 19-33, step **2**). Phosphorylated H2AX acts as a landing pad for recruiting additional protein complexes that control DNA repair in a manner that is conceptually similar to other aspects of cell cycle progression and control described in previous sections. That is, by using additional protein phosphorylations, recruiting additional proteins through phospho-binding domains, and marking proteins at the damage site, including H2AX using ubiquitin protein ligases (Figure 19-33, step **3**), as well as other protein modifications like methylation. The end result is the recruitment of two proteins that determine what specific type of DNA repair occurs at the break. One type of repair is *homologous recombination*, as described in Chapter 5. This involves the creation of single-stranded overhangs that in turn recruit and activate ATR and its effectors, further enhancing the DNA damage response. Repair by this process requires the presence of a homologous chromosome and so is restricted to late S and G_2 phases of the cell cycle. This type of repair requires a protein called *BRCA1* (Figure 19-33, step **4**). In contrast, recruitment of another protein called *53BP1* to the DNA break (Figure 19-33, step **5**) suppresses homologous recombination and promotes an alternative repair pathway known as *nonhomologous end joining*. Here the two

broken ends of the DNA are simply glued back together, sometimes with deletion of some of the DNA bases at the break joining site; hence this type of repair can be mutagenic. This end joining process requires the catalytic activity of DNA-PK. Since no homologous DNA sequence is required, nonhomologous end joining is the primary mechanism of repair for cells in G_1 and is also the dominant mechanism of repair in S and G_2, even though homologous DNA from chromosome replication is available. Other than cell cycle stage, we do not know what controls which repair pathway is used at a particular break.

FIGURE 19-33 Activation of cell cycle checkpoints and recruitment of repair machinery at DNA double-strand breaks. The activation and recruitment process depends on a concerted series of protein phosphorylations and ubiquitin modifications, together with recruitment of additional proteins through phosphoserine/threonine-binding domains and ubiquitin-binding modules. Step **1**: The ends of a double-strand break are recognized by the MRN complex, which activates ATM. The MRN complex also has nuclease activity that helps process the broken end for repair. Alternatively, the free double-stranded DNA end can bind to Ku70/80 (not shown) to activate DNA-PK. Step **2**: ATM, ATR, or DNA-PK phosphorylates the variant histone H2AX within nucleosomes located close to the break. This recruits additional proteins that recognize phospho-H2AX through their phospho-binding domains and are themselves then phosphorylated. Step **3**: One of the recruited phospho-binding proteins ubiquitinates H2AX. This allows H2AX to now bind to a ubiquitin-binding protein complex. Step **4**: Phosphorylation of the ubiquitin-binding complex recruits BRCA1 through its phospho-binding BRCT domains, which promotes homologous recombination. Step **5**: Alternatively, methylated histones on histone H4 near the break recruit 53BP1 through its methyl lysine-binding domain. Together with the catalytic activity of DNA-PK (not shown), this suppresses DNA end resection at the break, blocking homologous recombination and promoting nonhomologous end joining.

The identification of BRCA1 as a molecule involved in DNA repair emerged from genetic studies of breast-cancer prone families in whom the development of breast tumors showed a Mendelian-like pattern of inheritance. The genomic locus associated with this trait was localized to a single gene on chromosome 17 by Mary-Claire King and colleagues and designated *BR*east *C*ancer *A*ssociated-*1* (BRCA1). The gene was subsequently cloned by several academic and industrial research teams and shown to be mutated in the patients with breast cancer. Subsequent work by many labs

implicated the BRCA1 protein as a key component of the homologous DNA repair pathway. Cancer-associated mutations in BRCA1 disrupt its DNA repair function. ■

Downstream from ATR and ATM, the kinases Chk1, Chk2, and MK2 halt the cell cycle (see Figure 19-32). These protein kinases inhibit Cdc25 family members by phosphorylating them on sites that are distinct from the CDK-activating phosphorylation sites. These damage-induced phosphorylation sites target Cdc25 proteins to bind to various phosphoserine/threonine-binding proteins (Figure 19-34). When the DNA damage occurs during G_1, phosphorylation of Cdc25A targets it for binding to an F-box–containing ubiquitin-protein ligase (see Figure 19-14), targeting Cdc25A for proteasomal degradation. Loss of Cdc25A inhibits G_1/S phase CDKs and S phase CDKs (see Figure 19-34). As a result, these kinases cannot initiate DNA replication. When the DNA damage occurs during S phase or in G_2, phosphorylation of Cdc25B and Cdc25C by Chk1/2 and MK2 targets them for binding to 14-3-3 proteins. This reduces the catalytic activity of Cdc25B and Cdc25C and sequesters them, preventing them from binding to and activating mitotic CDKs, which results in arrest in G_2 (see Figures 19-34 and 19-21).

FIGURE 19-34 Overview of DNA damage checkpoint controls in the cell cycle. In response to DNA damage, the ATM or ATR protein kinases (ATM/R) inhibit Cdc25 family members via the Chk1/2 and MK2 protein kinases. They also activate p53, which induces production of the CKI p21. During G_1, the p53-p21 pathway inhibits G_1 CDKs. In S and G_2 replication stress (slow DNA replication fork movement or DNA replication fork collapse), activates the ATR-Chk1 protein kinase cascade, while DNA double-strand breaks activate the ATM-Chk2 protein kinase cascade. Chk1 and Chk2, together with MK2, phosphorylates and inactivates Cdc25B and C, blocking activation of mitotic CDKs and entry into mitosis. During G_1 and S, the DNA damage checkpoint pathways also phosphorylate Cdc25A, targeting it for $SCF^{\beta TrCP}$ -mediated degradation, thereby inhibiting G_1/S phase CDKs and S phase CDKs and blocking entry into or passage through S phase. Red symbols indicate pathways that inhibit progression through the cell cycle.

Even in the absence of DNA damage, active DNA replication also inhibits entry into mitosis. ATR activates Chk1 and MK2 to inhibit Cdc25B/C until all replication forks complete DNA replication and disassemble. This mechanism makes the initiation of mitosis dependent on the completion of chromosome replication. Finally, cells also sense DNA replication stress that results in stalling or slowing of replication forks. Such stress triggers activation of the ATR-Chk1 checkpoint pathway and results in down-regulation of S phase CDK activity and prevents the firing of late-replicating origins. In addition, ATR also stabilizes the stalled fork so that resumption of DNA replication can ensue once the replication stress is resolved.

Chk1-, Chk2-, and MK2-mediated inhibition of Cdc25 phosphatases is not the only means of inhibiting cell cycle progression when there is DNA damage or incomplete replication. DNA damage also leads to the activation of p53, a transcription factor that induces expression of the gene encoding the CDK inhibitor p21. p21 binds to and inhibits all metazoan cyclin-CDK complexes. As a result, cells are arrested in G_1 and G_2 (see Figure 19-34).

The transcription factor **p53** is known as a tumor suppressor because its normal function is to limit cell proliferation in the face of DNA damage. This protein is extremely unstable and generally does not accumulate to high enough levels to stimulate transcription under normal conditions. The instability of p53 results from its ubiquitinylation by a ubiquitin-protein ligase called *Mdm2* and its

subsequent proteasomal degradation. Rapid degradation of p53 is inhibited by ATM and ATR, which phosphorylate p53 at a site that interferes with Mdm2 binding. This and other modifications of p53 in response to DNA damage greatly increase its ability to activate transcription of specific genes that help the cell cope with DNA damage, such as p21.

Under some circumstances, such as when DNA damage is extensive, p53 also activates expression of genes that lead to apoptosis, the process of programmed cell death (see Figure 19-32). In metazoans, the p53 response leading to induce apoptosis (see Chapter 22) evolved presumably to prevent the accumulation of multiple mutations that might convert a normal cell into a cancer cell. The dual role of p53 in both cell cycle arrest and induction of apoptosis may account for the observation that nearly all cancer cells have mutations in the *p53* gene or in the pathways that stabilize p53 in response to DNA damage (see Chapter 25). The consequences of mutations in *p53, ATM*, and *Chk2* provide dramatic examples of the significance of cell cycle checkpoint pathways to the health of a multicellular organism.

The Spindle Assembly Checkpoint Pathway Prevents Chromosome Segregation Until Chromosomes Are

Accurately Attached to the Mitotic Spindle

The *spindle assembly checkpoint pathway* is a global surveillance mechanism that ensures that all of the chromosomes are properly attached to spindle microtubules through amphitelic attachments before entry into anaphase occurs. If even a single kinetochore is unattached or not under tension, then anaphase is inhibited, since any attempt to pull the sister chromatids apart in the presence of such a defect would almost certainly lead to chromosome loss. As we saw in Section 19.5, the spindle assembly checkpoint pathway monitors for kinetochores that are not attached to spindle microtubules. Microtubule-kinetochore interactions that are under insufficient tension are destabilized by the protein kinase Aurora B, which phosphorylates the microtubule-binding component of the kinetochore, the Ndc80 complex. This leads to the loss of stable kinetochore-microtubule interactions that are then recognized by the spindle assembly checkpoint pathway. In this manner, the kinase activity of Aurora B at the level of individual chromosomes and the spindle assembly checkpoint pathway that surveys attachments of all of the chromosomes collaborate during every cell cycle to accurately ensure that every single pair of sister chromatids is attached to the mitotic spindle in the correct, bi-oriented manner.

Components of the spindle assembly checkpoint pathway bind to unoccupied microtubule binding sites at kinetochores and create an

anaphase inhibitory signal that ultimately inhibits APC/C^{Cdc20}. Recall that APC/C^{Cdc20} is the ubiquitin ligase that triggers cyclin B degradation, and the ubiquitinylation and subsequent degradation of securin, triggering the activation of separase to degrade cohesins, and entry into anaphase (see Figure 19-28). When a kinetochore is not attached to microtubules, the outer kinetochore component Knl1 is phosphorylated by the spindle assembly checkpoint pathway protein kinase Mps1 (Figure 19-35). This phosphorylation, in turn, recruits other checkpoint pathway components to the unattached kinetochore. Critical for the shutting down of APC/C^{Cdc20} is the recruitment and activation of the Mad1-Mad2 complex by unattached kinetochores. Importantly, the activated Mad1-Mad2 complex can convert inactive ("open") Mad2 molecules in the cytoplasm to an active ("closed") conformation that is capable of binding to and inhibiting APC/C^{Cdc20}. Mad2 bound to APC/C^{Cdc20} recruits additional checkpoint factors to the complex to form the mitotic checkpoint complex (MCC). The MCC then prevents APC/C^{Cdc20} from recognizing and ubiquitinylating substrates. This spindle assembly checkpoint pathway enables a single unattached kinetochore to inhibit all cellular Cdc20, and thus anaphase, until the kinetochore becomes properly associated with spindle microtubules.

FIGURE 19-35 The spindle assembly checkpoint pathway. The spindle assembly checkpoint pathway is active until every single kinetochore has attached properly to spindle microtubules. Step **1**: When a kinetochore is unattached, the outer kinetochore component Knl1 is phosphorylated by the checkpoint kinase Mps1. Phosphorylated Knl1 then binds the checkpoint protein kinase Bub1-Bub3 and the checkpoint protein BubR1. These three proteins, in turn, recruit the Mad1-Mad2 complex to the kinetochore. The Mad1-Mad2 complex bound to a kinetochore adopts the active closed form (shown as Mad2-C; step **2**) and has the ability to convert inactive open Mad2 (Mad2-O) in the cytoplasm into active closed Mad2 that is able to bind $\mathrm{APC/C^{Cdc20}}$ and inhibit it. Complete inhibition of $\mathrm{APC/C^{Cdc20}}$ requires the recruitment of the checkpoint factors Bub1-Bub3 and BubR1 into the complex. Together, these proteins form the mitotic checkpoint complex (MCC) that prevents $\mathrm{APC/C^{Cdc20}}$

from recognizing and ubiquitinylating its substrates. Silencing of the spindle assembly checkpoint pathway occurs once all kinetochores have attached to microtubules in a tension-generating manner. Protein phosphatase 1 then de-phosphorylates Knl1, thereby eliminating checkpoint protein binding sites at kinetochores. In addition, $\mathrm{p31}^{\mathrm{comet}}$ disassembles the MCC, allowing $\mathrm{APC/C}^{\mathrm{Cdc20}}$ to degrade mitotic cyclins and securin to trigger anaphase.

[Data from E. A. Foley and T. M. Kapoor, 2013, *Nat. Rev. Mol. Cell Biol.* **14**:25–37; and A. Mussachio, 2015, *Curr. Biol.* **25**:R1002–R1018.]

Once all chromosomes have attached to the mitotic spindle in the correct amphitelic manner, the spindle assembly checkpoint pathway must be silenced to allow $\mathrm{APC/C}^{\mathrm{Cdc20}}$ to degrade securin and initiate anaphase. Silencing of the spindle assembly checkpoint pathway occurs through multiple mechanisms. Protein phosphatase 1 de-phosphorylates Knl1, thereby eliminating checkpoint protein-binding sites at kinetochores. In addition, a protein known as $p31^{comet}$ disassembles the MCC, thereby activating $\mathrm{APC/C}^{\mathrm{Cdc20}}$ and initiating anaphase (Figure 19-35).

The spindle assembly checkpoint pathway is essential for viability in mice, highlighting the importance of this quality-control pathway during every cell division. If anaphase is initiated before both kinetochores of a replicated chromosome become attached to microtubules from opposite spindle poles, chromosomes are mis-segregated in a process called **nondisjunction**. The resulting condition, in which cells have either lost or gained whole chromosomes, is called **aneuploidy**. Aneuploidy has profound

effects on health and fitness. It leads to the misregulation of genes and can contribute to the development of cancer. When nondisjunction occurs during the meiotic division that generates a human egg or sperm, trisomy (gain of a chromosome) or monosomy (loss of a chromosome) can be the result. As we will see in Section 19.8, meiosis is especially prone to nondisjunction, which can lead to spontaneous abortions or Down syndrome. ■

KEY CONCEPTS OF SECTION 19.7

Surveillance Mechanisms in Cell Cycle Regulation

- Surveillance mechanisms known as *checkpoint pathways* establish dependencies among cell cycle events and ensure that the next cell cycle event does not occur prior to the completion of a preceding event.
- Checkpoint pathways consist of sensors that monitor a particular cellular event, a signaling pathway, and an effector that halts cell cycle progression and activates repair pathways when necessary. These pathways make extensive use of protein kinases, phospho-binding domains, and ubiquitin-protein ligases.
- Cells are able to detect and respond to a wide variety of DNA damage, and their response depends on what stage of the cell cycle cells are in (see Figure 19-34).
- In response to DNA damage, three related protein kinases, DNA-PK, ATM, and ATR, are recruited to the damage site, where they activate signaling pathways that lead to cell cycle arrest, repair, and under some circumstances, apoptosis. ATM and ATR establish cell cycle checkpoints through the actions of three effector checkpoint kinases Chk1, Chk2, and MK2 (see Figure 19-32).
- The spindle assembly checkpoint pathway, which prevents premature initiation of anaphase, utilizes Mad2 and other proteins to regulate $\mathrm{APC/C}^{\mathrm{Cdc20}}$, which targets securin and mitotic cyclins for ubiquitinylation (see Figure 19-35).

19.8 Meiosis: A Special Type of Cell Division

In nearly all diploid eukaryotes, **meiosis** is the form of nuclear division that generates haploid germ cells — eggs or sperm. An egg or sperm from one individual can then fuse with a germ cell from another individual to generate a diploid zygote that develops into a new individual. Meiosis is a fundamental aspect of the evolution of eukaryotes because it results in the reassortment of the chromosome sets received from an individual's two parents. Chromosome reassortment and homologous recombination between parent DNA molecules during meiosis guarantee that each haploid germ cell will receive a unique combination of alleles that is distinct from each parent and from every other haploid germ cell formed. Meiosis, like mitosis, is preceded by a G_1, S, and G_2 phase.

The mechanisms of meiosis are analogous to those of mitosis. However, several features of meiosis generate genetically diverse haploid cells (see Figure 6-3). In the mitotic cell cycle, each S phase is followed by chromosome segregation and cell division. In contrast, during meiotic cell division, one round of DNA replication is followed by *two consecutive chromosome segregation phases*. This leads to the formation of haploid daughter cells. During the two divisions, maternal and paternal chromosomes are shuffled so that the daughter cells are different in genetic makeup from the parent cell. In this section, we discuss the similarities between mitosis and

meiosis and the meiosis-specific mechanisms that transform the canonical mitotic cell cycle machinery so that it leads to the formation of haploid daughter cells.

Extracellular and Intracellular Cues Regulate Germ Cell Formation

Identifying signals triggering entry into meiosis in metazoans is an active area of research. We know that extracellular signals induce a transcriptional program, which produces meiosis-specific cell cycle factors that bring about the meiotic cell divisions. This modification of the cell cycle goes hand in hand with a program that induces characteristic features of gametes, such as the development of a flagellum in sperm or the production of a stress-resistant cell wall in fungi. One of the extracellular signals inducing entry into meiosis in mammals is retinoic acid. Binding of retinoic acid to the retinoic acid receptor initiates activation of many different developmental processes (see Figure 9-43). The cellular targets of this hormone and how it functions to specify the meiotic fate remain to be discovered.

The molecular mechanisms underlying the decision to enter meiosis are well understood in *S. cerevisiae*. The decision to enter the meiotic divisions is made in G_1. Depletion of nitrogen and carbon sources induces diploid cells to undergo meiosis instead of mitosis, yielding haploid spores (see Figure 1-24). During the meiotic

divisions, budding is repressed. Pre-meiotic S phase and the two meiotic divisions thus occur within the confines of the parent cell. Spore walls are produced around the four meiotic products. Recall that budding and the initiation of DNA replication are induced by G_1/S phase CDKs. Their expression needs to be inhibited to prevent budding. Nutritional starvation represses expression of G_1/S phase cyclins, thereby inhibiting budding. However, DNA replication also relies on G_1/S phase CDKs. How can pre-meiotic DNA replication occur in the absence of G_1/S phase CDKs? The sporulation-specific protein kinase *Ime2* takes over the role of G_1/S phase CDKs in promoting DNA replication. Ime2 promotes (1) phosphorylation of the APC/C specificity factor Cdh1, inactivating it so that S phase and M phase cyclins can accumulate (see Figure 19-17); (2) phosphorylation of transcription factors to induce expression of genes whose products are required for S phase, including DNA polymerases and S phase cyclins (see Figure 19-18); and (3) phosphorylation of the S phase CDK inhibitor Sic1, leading to release of active S phase CDKs and the onset of pre-meiotic DNA replication.

Several Features Distinguish Meiosis from Mitosis

The meiotic divisions differ in several ways from mitotic divisions. These differences are summarized in Figure 19-36. The two

consecutive cycles of cell division are termed *meiosis I* and *meiosis II* (Figure 19-37). Meiosis II resembles mitosis in that sister chromatids are segregated. However, meiosis I is very different. During this division, homologous chromosomes — the chromosome inherited from your mother and the same chromosome inherited from your father — are segregated. This unusual chromosome segregation requires three meiosis-specific modifications to the chromosome segregation machinery. Next we discuss these modifications and explain why they are needed.

FIGURE 19-36 Comparison of the main features of mitosis and meiosis. See text for details.

FIGURE 19-37 Meiosis. Pre-meiotic cells have two copies of each chromosome (2*n*), one derived from the paternal parent and one from the maternal parent. For simplicity, the paternal and maternal homologs of only one chromosome are diagrammed. Step **1**: All chromosomes are replicated during S phase before the first meiotic division, giving a 4*n* chromosomal complement. Cohesin complexes (not shown) link the sister chromatids composing each replicated chromosome along their full lengths. Step **2**: As chromosomes condense during the first meiotic prophase, the replicated homologs pair and undergo homologous recombination, leading to at least one crossover event. At metaphase I, shown here, both chromatids of one chromosome associate with microtubules emanating from one spindle pole, but each member of a homologous chromosome pair associates with microtubules emanating from opposite poles. Step **3**: During anaphase of meiosis I, the homologous chromosomes, each consisting of two chromatids, are pulled to opposite spindle poles, and the chiasmata are dissolved as the recombination between homologous chromosomes is completed. Step **4**: Cytokinesis yields two daughter cells (now 2*n*), which enter meiosis II without undergoing DNA replication. At metaphase of meiosis II, shown here, the sister chromatids associate with spindle microtubules from opposite spindle poles, as they do in mitosis. Steps **5** and **6**: Segregation of sister chromatids to opposite spindle poles during anaphase of meiosis II, followed by cytokinesis, generates haploid gametes (1*n*) containing one copy of each chromosome. Micrographs on the left show meiotic metaphase I and metaphase II in developing gametes from *Lilium* (lily) ovules. Chromosomes are aligned at the metaphase plate.

The tension-based sensing mechanism responsible for accurately attaching chromosomes to the spindle during mitosis is also responsible for segregating chromosomes during meiosis I. Thus homologous chromosomes must be linked so that this tension-based

mechanism can function. Homologous recombination between homologous chromosomes creates these linkages (see Figure 19-36). The molecular mechanisms of homologous recombination are discussed in detail in Chapter 4. Here we restrict our discussion to the importance of homologous recombination to successful meiotic divisions.

In G_2 and prophase of meiosis I, the two replicated chromatids of each chromosome are linked together by cohesin complexes along the full length of the chromosome arms, just as they are following DNA replication in a mitotic cell cycle. In prophase of meiosis I, homologous chromosomes (i.e., the maternal and paternal chromosome 1, the maternal and paternal chromosome 2, etc.) pair with each other and undergo homologous recombination. The pairing of homologous chromosomes with each other, a unique feature of meiosis, is called *synapsis*, and is mediated by a proteinaceous complex known as the **synaptonemal complex (SC)** that initially forms at specific points on the chromosomes and spreads all along their lengths. This pairing precisely aligns the genes of homologous chromatids adjacent to one another in order to support homologous recombination. Significantly, at least one recombination event must occur between a maternal and a paternal chromosome. *Crossing over* of chromatids produced by recombination occurs at large multiprotein assemblies, called *recombination nodules*, and can be observed microscopically in the first meiotic prophase and metaphase as structures called *chiasmata*

(singular, *chiasma*). Homologous chromosomes are linked through chiasmata by a meiotic-specific cohesin called *Rec8* and are called *bivalents* (see Figure 19-36). During the later part of prophase, the synaptonemal complex is disassembled as the chromosomes condense until the homologous chromosomes are only attached at the chiasmata and adjacent cohesin molecules, which now provide the resistance to the pulling force exerted by microtubules on the metaphase I spindle (see Figure 19-37). At the meiotic metaphase to anaphase transition, Rec8 is cleaved by separase, much like how the mitotic cohesin Scc1 is cleaved by separase during mitosis, allowing the homologous chromosome pairs to separate.

Recombination between homologous chromosomes that occurs in prophase of meiosis I has two functional consequences: first, it contributes to genetic diversity among individuals of a species by ensuring new combinations of alleles in different individuals; second, it connects homologous chromosomes during meiosis I metaphase. The homologs, now connected through at least one chiasma, must align on the spindle in metaphase of meiosis I so that maternal and paternal chromosomes segregate away from each other during anaphase of meiosis I.

Recombination and a Meiosis-Specific Cohesin Subunit Are Necessary for the

Specialized Chromosome Segregation in Meiosis I

As we have seen, in metaphase of meiosis I, both sister chromatids in one (replicated) chromosome associate with microtubules emanating from the *same* spindle pole, rather than from opposite poles as they do in mitosis (Figure 19-38). Two physical links between homologous chromosomes resist the pulling force of the spindle until anaphase: (1) the chiasmata that result from crossing over between chromatids, and (2) cohesins distal to the crossover point (see Figure 19-39b, *top*). Evidence for the linking function of recombination during meiosis comes from the observation that when recombination is blocked by mutations in proteins essential for the process, chromosomes segregate randomly during meiosis I; that is, homologous chromosomes do not necessarily segregate to opposite spindle poles.

FIGURE 19-38 Chiasmata and cohesins distal to them link homologous chromosomes in meiosis I metaphase. Connections between chromosomes during meiosis I are most easily visualized in organisms with acrocentric centromeres, such as the grasshopper. The kinetochores at the centromeres of sister chromatids attach to spindle microtubules emanating from the same spindle pole, with the kinetochores of the maternal (red) and paternal (blue) chromosomes attaching to spindle microtubules from opposite spindle poles. The maternal and paternal chromosomes are attached to each other by chiasmata, which are formed by recombination between them and by the cohesion between sister chromatid arms that persists until metaphase I. Note that elimination of cohesion between sister chromatid arms by separase cleavage of the meiotic cohesin Rec8 is all that is required for the homologous chromosomes to separate at anaphase. See L. V. Paliulis and R. B. Nicklas, 2000, *J. Cell Biol.* **150**:1223–1232; and S. B. C. Buonomo et al., 2000, *Cell* **103**:387–398.

FIGURE 19-39 Cohesin function during mitosis and meiosis. (a) During mitosis, sister chromatids generated by DNA replication in S phase are initially linked by cohesin complexes along the length of the chromatids. During chromosome condensation, cohesin complexes (yellow) become restricted to the region of the centromere at metaphase. Shugoshin (purple) recruits PP2A to centromeres, where they antagonize Polo kinase and Aurora B, preventing the dissociation of cohesins from centromeric regions. Dissociation of Shugoshin from centromeres and activation of separase lead to removal of cohesins at the centromere. Sister chromatids now separate, marking the onset of anaphase.

(b) In prophase of meiosis I, maternal and paternal chromatids establish linkages between each other by homologous recombination. By metaphase I, the chromatids of each replicated chromosome are cross-linked by cohesin complexes along their full length. Rec8, a meiosis-specific homolog of Scc1, is cleaved along chromosome arms but not around the centromere, allowing homologous chromosome pairs to segregate to daughter cells. Centromeric Rec8 is protected from cleavage by PP2A, recruited to centromeric regions by the PP2A regulator Shugoshin (shown in purple). By metaphase II, the Shugoshin-PP2A complex dissociates from chromosomes. Cohesins can now be cleaved during meiosis II, allowing sister chromatids to segregate. See F. Uhlmann, 2001, *Curr. Opin. Cell Biol.* **13**:754–761.

At the onset of meiotic anaphase I, cohesins between chromosome arms are cleaved by separase. This cleavage is required for homologous chromosomes to segregate. If cohesins were not lost from chromosome arms, the recombined sister chromatids would be torn apart during anaphase I. The maintenance of centromeric cohesion during meiosis I is necessary for the proper segregation of sister chromatids during meiosis II.

Studies in many organisms have shown that a specialized cohesin subunit, *Rec8*, is necessary for the stepwise loss of cohesins from chromosomes during meiosis. Expressed only during meiosis, Rec8 is homologous to Scc1, the cohesin subunit that closes the cohesin ring in the cohesin complex of mitotic cells (see Figure 19-20). Immunolocalization experiments revealed that during early anaphase of meiosis I, Rec8 is lost from chromosome arms but is retained at centromeres. During early anaphase of meiosis II, centromeric Rec8 is cleaved by separase, so the sister chromatids

can segregate, as they do in mitosis (see Figure 19-39b, *bottom*). Consequently, understanding the regulation of Rec8-cohesin complex cleavage is central to understanding chromosome segregation in meiosis I.

Cohesin removal differs for meiosis I because when Rec8 replaces Scc1 in the cohesin complex, the complex does not dissociate in prophase when it is phosphorylated. The meiotic cohesin complex can be removed from chromatin only by the action of separase. To be cleaved by separase, Rec8, unlike Scc1, requires phosphorylation by several protein kinases. During meiosis I, the centromere-specific isoform of PP2A targeted to centromeric chromatin by Shugoshin prevents this phosphorylation. The PP2A targeting factor and PP2A then dissociate from chromosomes by metaphase II, allowing separase to cleave Rec8.

Meiosis I is much more error-prone than mitosis. It is estimated that 10 percent of all conceptions in humans are aneuploid. These aneuploidies are largely caused by chromosome nondisjunction in meiosis I. When recombination fails to take place between homologous chromosomes, or when the chiasmata are too close to the end of the chromosomes, either no tension or too little tension is exerted on kinetochore–microtubule attachments, and they are destabilized, leading to nondisjunction. As a result, eggs or sperm receive too few or too many chromosomes. All monosomies (lack of a chromosome) and most trisomies (gain of a chromosome) result in

embryonic lethality or death shortly after birth. Only trisomy 21, also known as *Down syndrome,* results in viable offspring, but it causes developmental abnormalities and intellectual disabilities.

Nondisjunction in meiosis I increases dramatically with maternal age. Whereas fewer than 0.1 percent of babies born to women under the age of 30 have Down syndrome, this rate increases to 3.5 percent at age 45. This increase in chromosome nondisjunction with maternal age is not specific to chromosome 21. The incidence of trisomy in clinically recognized pregnancies is less than 5 percent in women under 30 but is as high as 35 percent in women over the age of 42 (Figure 19-40). The reason for this dramatic increase in nondisjunction with maternal age lies in the biology of female meiosis in vertebrates. In all vertebrates, pre-meiotic DNA replication and recombination occur in the female embryo. The oocytes then become arrested in G_2 of meiosis I until the female reaches sexual maturity, which in humans is between the ages of 12 and 16. It is at this time that the first oocyte enters meiosis and progresses to the second meiotic metaphase, where it arrests and awaits fertilization (see Figure 19-5). The oocytes that enter the meiotic divisions in a 40-year-old woman have been arrested in G_2 for 40 years, during which time cohesins that hold the homologous chromosomes together during this very long G_2 phase can deteriorate, causing the homologous chromosomes to dissociate from each other. This can cause the homologous chromosomes to mis-segregate, leading to the formation of aneuploid eggs.

FIGURE 19-40 Fetal aneuploidy increases with maternal age. The percentage of trisomic embryos identified among clinically recognized pregnancies is shown as a function of maternal age.

[Data from T. Hassold and P. Hunt, 2001, *Nat. Rev. Genet.* **2**:280–291.]

Co-orienting Sister Kinetochores Is Critical for Meiosis I Chromosome

Segregation

At metaphase in mitosis and meiosis II, sister kinetochores attach to spindle microtubules emanating from opposite spindle poles; the kinetochores are said to be *bi-oriented*. This is essential for segregation of sister chromatids to different daughter cells. In contrast, at meiosis I metaphase, sister kinetochores attach to spindle microtubules emanating from the same spindle pole; these sister kinetochores are said to be **co-oriented** (see Figure 19-38). Obviously, attachment of sister kinetochores to the proper microtubules in meiosis I and II is critical for correct meiotic segregation of chromosomes.

Proteins required for meiosis I sister kinetochore co-orientation were first identified in *S. cerevisiae*. In this organism, a single microtubule attaches to each kinetochore. We now know that a protein complex known as the **monopolin complex** associates with sister kinetochores during meiosis I and fuses them into a single kinetochore unit, to which one microtubule attaches. In all other organisms, kinetochores attach to multiple microtubules. In vertebrates, Rec8-containing cohesins are essential for sister kinetochore co-orientation. These meiosis-specific cohesins impose a rigid kinetochore structure, restricting the movement of sister kinetochores and thereby favoring their attachment to microtubules from the same spindle pole.

Correct attachment of meiosis I chromosomes is mediated by a tension-based mechanism, as it is during mitosis and meiosis II. During meiotic metaphase I, kinetochore-associated microtubules are under tension (even though the co-oriented kinetochores of sister chromatids attach to microtubules coming from the same spindle pole) because chiasmata generated by recombination between homologous chromosomes and the cohesins distal to the chiasmata prevent them from being pulled to the poles (see Figure 19-38). Since kinetochore-microtubule attachments are unstable in the absence of tension (due to Aurora B–mediated phosphorylation), kinetochores that attach to microtubules from the wrong spindle release those microtubules, which enables them to bind microtubules again until attachments are made that generate tension. As in mitosis, once tension is generated, microtubule attachment to the kinetochores is stabilized.

KEY CONCEPTS OF SECTION 19.8

Meiosis: A Special Type of Cell Division

- Meiosis is a specialized type of cell division in which meiosis-specific gene products modulate the mitotic cell division program (see Figure 19-36).
- The meiotic division comprises one cycle of chromosome replication followed by two cycles of cell division to produce haploid germ cells from a diploid pre-meiotic cell. During meiosis I, homologous chromosomes are segregated; during meiosis II, sister chromatids separate.
- Specialized environmental conditions induce a developmental program that leads to the meiotic divisions.
- During prophase of meiosis I, homologous chromosomes pair with each other and undergo recombination. At least one recombination event must occur between the

chromatids of each pair of homologous chromosomes for proper chromosome segregation (see Figure 19-37).

- Chiasmata and cohesins distal to them are responsible for holding the homologous chromosomes together during prophase and metaphase of meiosis I (see Figure 19-38).
- At the onset of anaphase of meiosis I, cohesins on chromosome arms are phosphorylated and, as a result, cleaved by separase, but cohesins in the region of the centromere are protected from phosphorylation and cleavage. This protection is brought about by a meiosis-specific cohesin subunit and a protein phosphatase that associates with centromeres. As a result, the sister chromatids remain linked to each other during segregation in meiosis I (see Figure 19-39).
- Cleavage of centromeric cohesins during anaphase of meiosis II allows individual chromatids to segregate into germ cells (see Figure 19-39).
- Meiotic cohesins facilitate the attachment of sister kinetochores to microtubules emanating from the same pole during meiosis I.

Review the Concepts

1. What cellular mechanism(s) ensure that passage through the cell cycle is unidirectional and irreversible? What molecular machinery underlies these mechanism(s)?
2. What types of experimental strategies do researchers employ to study cell cycle progression? How do genetic and biochemical approaches to this topic differ?
3. Tim Hunt shared the 2001 Nobel Prize in Physiology or Medicine for his work in the discovery and characterization of cyclin proteins in eggs and embryos. Describe the experimental steps that led him to his discovery of cyclins.
4. What physiological differences between *S. pombe* and *S. cerevisiae* make them useful yet complementary tools for studying the molecular mechanisms involved in cell cycle regulation and control?
5. In *Xenopus*, one of the substrates of mitotic CDKs is the phosphatase Cdc25. When phosphorylated by mitotic CDKs, Cdc25 is activated. What is the substrate of Cdc25? How does this information help to explain the rapid rise in mitotic CDK activity as cells enter mitosis?
6. Explain how CDK activity is modulated by the following proteins: (a) cyclin, (b) CAK, (c) Wee1, (d) p21.
7. Explain the role of CDK inhibitors. If cyclin-CDK complexes are necessary to allow regulated progression through the eukaryotic cell cycle, what would be the physiological rationale for CDK inhibitors?

8. Cancer cells typically lose cell cycle entry control. Explain how the following mutations, which are found in some cancer cells, lead to a bypass of these controls: (a) overexpression of cyclin D, (b) loss of Rb function, (c) loss of p16 function, (d) hyperactive E2F.
9. The Rb protein has been called the "master brake" of the cell cycle. Describe how the Rb protein acts as a cell cycle brake. How is the brake released in mid to late G_1 to allow the cell to proceed to S phase?
10. A common feature of cell cycle regulation is that the events of one phase ensure progression to a subsequent phase. In *S. cerevisiae*, G_1 and G_1/S phase CDKs promote S phase entry. Name two ways in which they promote the activation of S phase.
11. For S phase to be completed in a timely manner, DNA replication must be initiated from multiple origins in eukaryotes. In *S. cerevisiae*, what role do S phase CDKs and DDKs play to ensure that the entire genome is replicated once and only once per cell cycle?
12. In 2001, the Nobel Prize in Physiology or Medicine was awarded to three cell cycle scientists. Paul Nurse was recognized for his studies with the fission yeast *S. pombe*, in particular for the discovery and characterization of the $wee1^+$ gene. What did the characterization of the $wee1^+$ gene tell us about cell cycle control?
13. What role do phosphoserine/threonine-binding proteins play in controlling entry from G_1 into S phase and entry from G_2 into M phase?

14. Describe how cells know whether sister kinetochores are properly attached to the mitotic spindle.
15. Describe the series of events by which APC/C promotes the separation of sister chromatids at anaphase.
16. Describe how cytokinesis is regulated so that cell cleavage only occurs after chromosome separation.
17. Leland Hartwell, the third recipient of the 2001 Nobel Prize in Physiology or Medicine, was acknowledged for his characterization of cell cycle checkpoint pathways in the budding yeast *S. cerevisiae*. What is a cell cycle checkpoint pathway? When during the cell cycle do checkpoint pathways function? How do cell cycle checkpoint pathways help to preserve the genome?
18. What role do tumor suppressors, including p53, play in mediating cell cycle arrest for cells with DNA damage?
19. Individuals with the hereditary disorder ataxia telangiectasia suffer from neurodegeneration, immunodeficiency, and an increased incidence of cancer. The genetic basis for ataxia telangiectasia is a loss-of-function mutation in the gene encoding ATM (*ATM; a*taxia *t*elangiectasia *m*utated). Besides p53, what other substrate is phosphorylated by ATM? How does the phosphorylation of this substrate lead to inactivation of CDKs to enforce cell cycle arrest?
20. Overall, meiosis and mitosis are analogous processes involving many of the same proteins. However, some proteins function uniquely in each of these cell-division

events. Explain the meiosis-specific function of the following: (a) Ime2, (b) Rec8, (c) monopolin.

21. Explain why the incidence of Down syndrome increases with maternal age.

CHAPTER 20

Integrating Cells into Tissues

Image courtesy of B. L. Song.

Antibody staining of mouse small intestinal villi, fingerlike projections of cell layers (see Figures 20-13 through 20-15). NPC1L1, a protein located primarily on the plasma membrane involved with cholesterol metabolism, is green. Villin, which binds to actin bundles in

microvilli (very small membrane projections on the apical surfaces of absorptive cells that take up digested nutrients), is red. Nuclei (DNA) are blue. The image shows all colors merged together (colocalization of green and red appears yellow). The yellow lines show how the apical surfaces of the cells face the lumen of the small intestine (black) from which nutrients are absorbed.

OUTLINE

20.1 Cell-Cell and Cell–Extracellular Matrix Adhesion: An Overview
20.2 Cell-Cell and Cell–Extracellular Matrix Junctions and Their Adhesion Molecules
20.3 The Extracellular Matrix I: The Basal Lamina
20.4 The Extracellular Matrix II: Connective Tissue
20.5 Adhesive Interactions in Motile and Nonmotile Cells
20.6 Plant Tissues

In the development of complex multicellular organisms such as plants and animals, progenitor cells differentiate into distinct *types* that have characteristic compositions, structures, and functions. Cells of a given type often aggregate into a *tissue* to cooperatively perform a common function — muscle contracts, neural tissue conducts electric impulses, xylem tissue in plants transports water. Different tissues can be organized into an *organ*, again to perform one or more specific functions. For instance, the muscles, valves, and blood vessels of a heart work together to pump blood. The coordinated functioning of many types of cells and tissues permits the organism to move, metabolize, reproduce, and carry out other essential activities. Indeed, the complex and diverse morphologies of plants and animals are examples of the whole being greater than the sum of the individual parts.

Vertebrates have many hundreds of different cell types, including leukocytes (white blood cells) and erythrocytes (red blood cells), photoreceptors in the retina, fat-storing adipocytes, fibroblasts in connective tissue, and the hundreds of different subtypes of neurons in the human brain. A large-scale international effort, the Human Cell Atlas Project, is using single-cell RNA sequencing and other methods to generate a comprehensive catalogue of all human cell types and subtypes.

Multicellular animals — also called *metazoans* — usually comprise differentiated cells organized into distinct tissues, although there are some less complex exceptions (e.g., sponges). Even rather simple animals exhibit distinctive tissue organization. The adult form of the roundworm *Caenorhabditis elegans* contains a mere 959 cells, yet these cells fall into 12 different general cell types and many distinct subtypes. Despite their diverse forms and functions, animal cells typically can be classified as components of just five main classes of tissue: *epithelial tissue*, *connective tissue*, *muscular tissue*, *neural tissue*, and *blood*. Various cell types are arranged in precise patterns of staggering complexity to generate tissues and organs. The physiological costs of such complexity include increased requirements for information, material, energy, and time during the development of an individual organism. Although these costs of generating and maintaining complex tissues and organs are high, they confer the ability to thrive in varied and variable environments — a major evolutionary advantage.

One of the defining characteristics of animals with complex tissues and organs (most metazoans) is that the external and internal surfaces of most of their tissues and organs — and indeed, the exterior of the entire organism — are built from tightly packed sheet-like layers of cells known as **epithelia**. The formation of an epithelium and its subsequent remodeling into more complex collections of epithelial and nonepithelial tissues is a hallmark of the development of most metazoans. Sheets of tightly attached epithelial cells act as regulatable, selectively permeable barriers, which permit the generation of chemically and functionally distinct compartments in an organism, such as the stomach and bloodstream. As a result, distinct and sometimes opposite functions (e.g., digestion and synthesis) can efficiently proceed simultaneously within an organism. Such compartmentalization also permits more sophisticated regulation of diverse biological functions. In many ways, the roles of complex tissues and organs in an organism are analogous to those of organelles and membranes in individual cells.

The assembly of distinct tissues and their organization into organs are determined by molecular interactions at the cellular level (Figure 20-1). These interactions would not be possible without the temporally, spatially, and functionally regulated expression of a wide array of adhesion molecules. Cell-surface molecules engaged in adhesion are called **adhesion receptors**. Cells in tissues can adhere directly to one another (*cell-cell adhesion*) through specialized

membrane proteins called **cell-adhesion molecules (CAMs)** or **cell-cell adhesion receptors**, which often cluster on the plasma membrane, sometimes into specialized structures called **cell junctions**. In the fruit fly *Drosophila melanogaster*, at least 500 genes (~4 percent of the total) are estimated to be involved in cell adhesion, and in mammals there are over 1000 such genes. Cells in animal tissues also adhere indirectly (*cell-matrix adhesion*) through the binding of **cell-matrix adhesion receptors** in the plasma membrane to components of the surrounding **extracellular matrix (ECM)**, a complex interdigitating meshwork of proteins and polysaccharides secreted by cells into the spaces between them. Some classes of adhesion receptors (e.g., integrins) can mediate both cell-cell adhesion as well as cell-matrix adhesion.

FIGURE 20-1 Overview of major cell-cell and cell-matrix adhesive interactions. Schematic cutaway drawing of a typical epithelial tissue, such as in the inner surface of the intestines. The apical (upper) surface of each cell is packed with fingerlike microvilli (**1**) that project into the intestinal lumen; the basal (lower) surface (**2**) rests on extracellular matrix (ECM). The ECM (**3**) associated with epithelial cells is usually organized into various interconnected layers — such as the basal lamina (**3a**), connecting fibers (not shown), and connective tissue (**3b**) — in which large, interdigitating ECM macromolecules bind to one another and to the cells (**3**). Cell-adhesion molecules (CAMs, also called *cell-cell adhesion receptors*) bind to CAMs on other cells, mediating cell-cell adhesion (**4**), and cell-matrix adhesion receptors bind to various components of the ECM, mediating cell-matrix adhesion (**5**). Both types of adhesion receptors are usually integral membrane proteins whose cytosolic domains often bind to multiple intracellular adapter proteins. These adapters, directly or indirectly, link the CAM to the cytoskeleton (actin or intermediate filaments) and to intracellular signaling pathways (see Figure 20-8). As a consequence, information can be transferred by adhesion receptors and the macromolecules to which they bind from the cell exterior to the intracellular environment and vice versa. In some cases, a complex aggregate of adhesion receptors, adapters, and associated proteins is assembled. Specific, localized aggregates of adhesion receptors form various types of cell junctions, which play important roles in holding tissues together and facilitating communication between cells and their environment. Tight junctions (**6**), lying just under the apical surface, prevent the diffusion of many substances through the extracellular spaces between the cells. Through connexon channels, gap junctions (**7**) allow the movement of small molecules and ions between the cytosols of adjacent cells. The remaining three types of junctions, adherens junctions (**8** and **4**), desmosomes (**9**), hemidesmosomes (**10** and **5**), and focal adhesions (also called *focal contacts*; **11**) link the cytoskeleton of a cell to other cells or to the ECM. See V. Vasioukhin and E. Fuchs, 2001, *Curr. Opin. Cell Biol.* **13**:76–84.

Cell-cell and cell-matrix adhesions not only allow cells to aggregate into distinct tissues, but also provide a means for the bidirectional transfer of information between the exterior and the interior of cells. As we will see, both types of adhesions are intrinsically associated with the cytoskeleton and cellular signaling pathways. As

a result, a cell's surroundings influence its shape and functional properties ("outside-in" effects); likewise, cellular shape and function influence a cell's surroundings ("inside-out" effects). Thus *connectivity* and *communication* are intimately related properties of cells in tissues. Information transfer is important to many biological processes, including cell survival, proliferation, differentiation, and migration. Therefore, it is not surprising that defects that interfere with adhesive interactions and the associated flow of information can cause or contribute to diseases, including a wide variety of neuromuscular and skeletal disorders, heart and vascular defects, clotting abnormalities, cancer, and others.

In this chapter, we examine various types of adhesion molecules found on the surfaces of cells and in the surrounding extracellular matrix. Interactions between these molecules allow the organization of cells into tissues and have profound effects on tissue development, function, and pathology. Many adhesion molecules are members of families or superfamilies of related proteins. While each type of adhesion molecule performs a distinct role, we will focus on the common features shared by members of some of these families to illustrate the general principles underlying their structures and functions. Because of the particularly well-understood nature of the adhesion molecules in tissues that form tight epithelia, as well as their very early evolutionary development, we will initially focus on epithelial tissues, such as the walls of the intestinal tract and the skin. Epithelial cells are normally nonmotile

(immobile), also called *sessile*; however, during development, wound healing, and in certain pathological states (e.g., cancer), epithelial cells can transform into motile cells. Changes in the expression and function of adhesion molecules play a key role in this transformation, as they do in normal biological processes involving cell movement, such as the crawling of white blood cells into sites of infection. We therefore follow the discussion of epithelial tissues with a discussion of adhesion in nonepithelial, developing, and motile tissues.

The evolutionary lineages of plants and animals diverged before multicellular organisms arose (see Figure 1-1). Thus multicellularity and the molecular means for assembling tissues and organs presumably arose independently in animal and plant lineages. Not surprisingly, then, animals and plants exhibit many differences in the organization and development of tissues. For this reason, we first consider the organization of tissues in animals and then deal separately with plants.

20.1 Cell-Cell and Cell–Extracellular Matrix Adhesion: An Overview

There are many different types of cells in the body that dynamically interact with each other in a myriad of ways. These interactions, achieved via adhesion molecules, must be precisely and carefully controlled in time and space and in their physical characteristics (e.g., strength of adhesion) to correctly determine the structures and functions of tissues in a complex organism. It is not surprising, therefore, that cell-cell and cell-matrix adhesion molecules exhibit diverse structures, or that their expression levels vary in different cells and tissues. As a consequence, they mediate the very specific and distinctive cell-cell and cell-matrix interactions that hold tissues together as well as permit essential communication between cells and their environment. We begin this overview with a brief orientation to some of the various types of adhesion molecules present on cells and within the extracellular matrix, their major functions in organisms, and their evolutionary origin. In subsequent sections, we will examine in detail the unique structures and properties of various participants in cell-cell and cell-matrix interactions.

Cell-Adhesion Molecules Bind to One Another and to Intracellular Proteins

Cell-cell adhesion is mediated through membrane proteins called *cell-adhesion molecules* (*CAMs*, also called *cell-cell adhesion receptors*). Many CAMs fall into one of four major families: the cadherins, the immunoglobulin (Ig) superfamily, the integrins, and sugar-binding proteins called *lectins*, one subset of which are called *selectins*. As the schematic structures in Figure 20-2 illustrate, CAMs often comprise multiple, distinct domains, many of which can be found in more than one kind of protein. The functions of these domains vary. Some confer the ability to bind specifically to their partner CAMs on neighboring cells or even to CAMs on the same cell. Some of these domains are present in multiple copies and contribute to the length of the CAMs and thus help define the distance between the plasma membranes of cells bound together by the CAMs. Other membrane proteins, whose structures do not belong to any of the major classes of CAMs in Figure 20-2, are also adhesion receptors and participate in cell-cell and cell-matrix adhesion in various tissues. One example is a set of adhesion G protein–coupled receptors (GPCRs, see Chapter 15). As we will see later, integrins can function both as cell-cell and cell-matrix adhesion receptors. Figure 20-2 depicts an integrin serving as a cell-matrix adhesion receptor that binds to ECM components. Some Ig-superfamily CAMs can play this dual role as well.

FIGURE 20-2 Major families of cell-adhesion molecules (CAMs) and adhesion receptors. Adhesion receptors can mediate binding, either by homophilic interactions (binding to other molecules of the same type; *left*) or heterophilic interactions (binding to different types of molecules; *right*). E-cadherins on one cell (light blue, cell 1) commonly mediate cell-cell adhesion by forming homophilic cross-bridges with identical E-cadherins on adjacent cells (dark blue, cell 2). E-cadherins also can bind to neighboring E-cadherin molecules on the same cells (see Figures 20-3 and 20-14). Members of the immunoglobulin (Ig) superfamily of adhesion receptors form homophilic linkages (as shown here for NCAM) or heterophilic linkages (to other types of CAMs, not shown). Heterodimeric integrins (e.g., αv and β3 chains) can function as cell-matrix adhesion receptors that bind to very large, multi-adhesive extracellular proteins such as fibronectin, only a small part of which is shown here. Selectins, shown as dimers, contain a carbohydrate-binding lectin domain that recognizes specialized sugar structures on glycoproteins (as shown here) or glycolipids on adjacent cells (heterophilic interactions). Note that CAMs such as E-cadherins, often form higher order oligomers within the plane of the plasma membrane. Many adhesion molecules contain multiple, distinct domains, some of which are found in more than one kind of CAM. The cytoplasmic domains of adhesion receptors are often associated with adapter proteins that link them to the cytoskeleton or to signaling pathways. See R. O. Hynes, 1999, *Trends Cell Biol.* **15**(12):M33–M37; R. O. Hynes, 2002, *Cell* **110**:673–687; and J. Brasch et al., 2012, *Trends Cell Biol.* **22**:299–310.

Through their extracellular domains, CAMs mediate adhesive interactions between cells of the same type (**homotypic adhesion**) or between cells of different types (**heterotypic adhesion**). A CAM on one cell can directly bind to the same kind of CAM on an adjacent cell (**homophilic binding**) or to a different class of CAM (**heterophilic binding**) (see Figure 20-2). CAMs can be broadly distributed along the regions of plasma membranes that contact other cells or clustered in discrete patches or spots that are sometimes called *cell junctions*. Cell-cell adhesions can be tight and long lasting or relatively weak and transient. For example, the associations between neurons in the spinal cord or the metabolic cells in the liver exhibit tight adhesion. In contrast, immune-system cells in the blood often exhibit only brief, weak interactions that allow them to roll along and pass through a blood vessel wall on their way to fight an infection within a tissue.

The cytosolic domains of adhesion receptors recruit sets of multifunctional **adapter proteins** (see Figure 20-1). These adapters act as linkers that directly or indirectly connect adhesion receptors to elements of the cytoskeleton (see Chapters 17 and 18); they can also recruit intracellular molecules that function in signaling pathways (see Chapters 15 and 16) to modify cellular behavior, including gene expression, and the activities of a variety of intracellular proteins including the adhesion receptors themselves. In many cases, a complex aggregate of adhesion receptors, adapter proteins, and other associated proteins is assembled at the inner

surface of the plasma membrane. These complexes facilitate two-way, outside-in and inside-out, communication between cells and their surroundings.

The formation of many cell-cell adhesions entails two types of molecular interactions, called *trans* and *cis* binding interactions (Figure 20-3). **Trans interactions** are also called **intercellular** or *adhesive* interactions, and **cis interactions** are also called **lateral** (in the same cell) interactions. In trans interactions, CAMs on one cell bind to the CAMs on an adjacent cell. In cis interactions, monomeric CAMs on one cell bind to one or more CAMs in the same cell's plasma membrane. For some adhesion molecules the trans interactions between adjacent cells can increase the probability of stable cis interaction formation and thus determine the order in which these interactions occur (trans prior to cis is shown in Figure 20-3). It appears that trans and cis interactions are mutually reinforcing. Furthermore, the association of intracellular molecules with the cytosolic domains of CAMs can dramatically influence the intermolecular interactions of CAMs by promoting their clustering together (e.g., cis interactions) or by altering their conformation in a way that increases the affinity of trans interactions. Just like Velcro, CAMs can generate very tight adhesion when many weak interactions are combined, and this is especially the case when CAMs are concentrated in small, well-defined areas such as cell junctions.

FIGURE 20-3 Model for the generation of cell-cell adhesions. Trans interactions between CAMs on adjacent cells can hold the plasma membranes closely together and permit the subsequent formation of cis (lateral) interactions that collect the CAMs into clusters. The parts of the molecules that participate in these trans and cis interactions vary among the different CAMs. Multiple trans interactions concentrated in space by cis interactions generate a strong, Velcro-like adhesion between the cells. The models shown here are based on CAMs called *classical cadherins* (described in greater detail later in this chapter). See M. S. Steinberg and P. M. McNutt, 1999, *Curr. Opin. Cell Biol.* **11**:554–560; and J. Brasch et al., 2012, *Trends Cell Biol.* **22**:299–310.

Adhesive interactions between cells and the consequences of those interactions on cell structure and function vary considerably, depending on the tissue and the particular CAMs participating. For example, some CAMs require calcium ions to form effective adhesions while others do not. Among the many variables that determine the nature of adhesion between two cells are: the binding affinity of the interacting molecules (thermodynamic properties); the overall “on” and “off” rates of association and dissociation for each interacting molecule (kinetic properties); the spatial

distribution or density of adhesion molecules (ensemble properties); the active versus inactive states of CAMs with respect to adhesion (biochemical properties); and external forces such as stretching and pulling, for example, in muscle or the laminar and turbulent flow of cells and surrounding fluids in the circulatory system (mechanical properties).

The Extracellular Matrix Participates in Adhesion, Signaling, and Other Functions

The ECM is a complex combination of proteins and polysaccharides that is secreted and assembled by cells into a network in which the components bind to one another. The ECM is often involved in holding cells and tissues together. The composition, physical properties, and functions of the ECM are carefully controlled and can vary depending on the tissue type, its location, its physiological state, and chemical modifications of its components, including changes that can occur as a consequence of pathology. These modifications include enzymatic phosphorylation, sulfation and desulfation, cross-linking, cleavage by proteases and glycosidases, and oxidation, as well as nonenzymatic addition of glucose (glycation).

The ECM is usually sensed by cells as a consequence of binding to cell-matrix adhesion receptors on their plasma membranes, which then instruct the cells to behave appropriately in response to their environments or modulate the structure and function of the ECM based on the state of the cells. Different cells can bind to the same patch of ECM via their adhesion receptors and thus be indirectly bound together. ECM components include proteoglycans, a unique type of glycoprotein (a protein with covalently attached sugars); collagens and other proteins that often form fibers; soluble multi-adhesive matrix proteins; and others (Table 20-1). A common feature of many ECM proteins is that they comprise repeating structural domains (sometimes called *repeats*) that form very large proteins. Within one molecule, these repeats can be either very similar (homologous) to other repeats in the protein, distinct from other repeats, or both. The presence of nonidentical repeats that can exhibit distinct binding properties contributes to the multiligand and multifunctional characteristics of many adhesive proteins. For example, multi-adhesive matrix proteins, such as fibronectin and laminin, are long, flexible molecules that contain multiple repeats. They are responsible for binding various types of collagen, other matrix proteins, polysaccharides, and extracellular signaling molecules as well as cell-matrix adhesion receptors. These proteins are important organizers of the extracellular matrix. Through their interactions with adhesion receptors, they also regulate cell-matrix adhesion — and thus cell shape and behavior.

TABLE 20-1 • Extracellular Matrix Proteins

Proteoglycans	Collagens	Multi-adhesive matrix proteins
Perlecan 	Sheet forming (e.g., type IV)  Fibrillar collagens (e.g., types I, II, and III) 	Laminin  Fibronectin  Nidogen/entactin 
Cells contribute to the assembly of the ECM not only by secreting its components, but also by participating directly in the assembly of those components into complex structures containing large fibrils and amorphous macromolecules. Once assembled, the ECM often is not static, but rather highly dynamic in that its chemical, physical, and biological properties can be altered quantitatively or qualitatively as a consequence of cells secreting enzymes, such as proteases, and other molecules into the extracellular space. These alterations in the ECM, which are usually referred to as *remodeling*, can involve covalent chemical modifications (including chemical cross-linking of ECM molecules), partial or essentially complete proteolytic cleavage of ECM components, and addition of newly synthesized ECM molecules. An example we have already encountered, and will discuss in more detail in Section 20.4, is the

role of ECM components in triggering activation of TGF-β by releasing it from its inhibitor (see Figure 16-22).

The relative volumes occupied by cells and their surrounding matrix vary greatly among different animal tissues. Some **connective tissue**, for instance, is mostly matrix with relatively few cells (Figure 20-4a), whereas many other tissues, such as epithelia, are composed of very densely packed cells with relatively little matrix (Figure 20-4b). The density of packing of the molecules within the ECM itself can also vary greatly.

FIGURE 20-4 Variation in the relative density of cells and ECM in different tissues. (a) Dense connective tissue contains mostly extracellular matrix consisting of tightly packed ECM fibers (pink) interspersed with rows of relatively sparse fibroblasts, the cells that synthesized this ECM (purple). (b) Squamous epithelium viewed from the top, showing epithelial cells tightly packed into a quilt-like pattern with the plasma membranes of adjacent cells close to one another and little ECM between the cells (see also Figure 20-10b).

H. V. Wilson's classic studies of adhesion in marine sponge cells showed conclusively that one primary function of the ECM is to

literally hold tissue together. Figures 20-5a and 20-5b, which re-create Wilson's classic work, show that when sponges are mechanically dissociated and individual cells from two sponge species are mixed, the cells of one species will adhere to one another, but not to cells from the other species. This specificity is due in part to species-specific adhesive proteins in the ECM that bind to the cells via adhesion receptors. These adhesive proteins can be purified and used to coat colored beads, which, when mixed, aggregate with one another with a specificity similar to that of intact sponge cells (Figure 20-5c, d).

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

EXPERIMENTAL FIGURE 20-5 Mechanically separated marine sponges reassemble through species-specific homotypic cell adhesion. (a) Two intact sponges, *Microciona prolifera* (orange) and *Halichondria panicea* (yellow), growing in the wild. (b) After mechanical disruption and mixing of the individual cells from the two sponge species, their individual cells were allowed to reassociate for about 30 minutes with gentle stirring. The cells aggregated

with species-specific homotypic adhesion, forming clumps of *M. prolifera* cells (orange) and *H. panicea* cells (yellow). In parts (c) and (d) red or green fluorescently labeled beads were coated with the proteoglycan aggregation factor (AF) from the ECM of either *M. prolifera* (MAF) or *H. panicea* (HAF). (c) When beads of both colors were coated with MAF, they all aggregated together, forming yellow aggregates (combination of red and green). (d) MAF (red) and HAF (green) coated beads do not readily form mixed aggregates, but rather assemble into distinct clumps held together by homotypic adhesion. (Magnification 40 ×.)

Commun.* **6**(5):405–414; © Taylor and Francis, www.tandfonline.com.]

The ECM plays a multitude of other roles in addition to facilitating cell adhesion (Table 20-2). Different combinations of components tailor the ECM for specific purposes at different anatomic sites, for example, strength in a tendon, strength and rigidity in teeth and bones, cushioning in cartilage, and transparency in the vitreous humor in the eyeball. The composition of the ECM also provides positional and signaling information for cells, letting a cell know where it is and what it should do. ECM remodeling can modulate the interactions of a cell with its environment. Furthermore, the ECM serves as a reservoir for many extracellular signaling molecules that control cell growth and differentiation. In addition, it provides a lattice through or on which cells either can move or are prevented from moving, particularly in the early stages of tissue assembly.

Morphogenesis — the stage of embryonic development in which tissues, organs, and body parts are formed by cell movements and rearrangements — is critically dependent on cell-matrix adhesion as well as cell-cell adhesion. For example, cell-matrix interactions are required for branching morphogenesis (formation of branching structures) to form blood vessels, the air sacs in the lung, mammary and salivary glands, and other structures (Figure 20-6).

TABLE 20-2 • Functions of the Extracellular Matrix

1. Anchoring and surrounding cells to maintain solid-tissue three-dimensional architecture and define tissue boundaries
2. Determining the biomechanical properties (stiffness/elasticity, porosity, shape) of the extracellular environment
3. Controlling cellular polarity, survival, proliferation, differentiation, and fate (e.g., asymmetric division of stem cells; see Chapter 22), and thus embryonic and neonatal development and adult function and responses to the environment and to disease
4. Inhibiting or facilitating cell migration (e.g., serving as either a barrier to movement or, conversely, as a “track” along which cells — or portions of cells — can move)
5. Binding to and acting as a reservoir of growth factors; in some cases, the ECM (a) helps generate an extracellular concentration gradient of the growth factor, (b) serves as a co-receptor for the growth factor, or (c) aids in proper binding of the growth factor to its receptor (ECM component and growth factor jointly serve as a receptor’s combined ligand)
6. Activating cell surface signaling receptors

EXPERIMENTAL FIGURE 20-6 Antibodies to fibronectin block branching morphogenesis in developing mouse tissues. Immature salivary glands were isolated from mouse embryos and allowed to undergo branching morphogenesis in vitro for 10 hours in the absence (a) or presence (b) of an antibody that binds to and blocks the activity of the ECM molecule fibronectin. Anti-fibronectin antibody (Anti-FN) treatment blocked branch formation (arrowheads). Inhibition of fibronectin's adhesion receptor (an integrin) also blocks branch formation (not shown). Scale bar, 100 μm.

Disruptions in cell-matrix and cell-cell interactions can have devastating consequences for the development of tissues. Figure 20-7 shows the dramatic changes in the skeletal system of embryonic mice when the genes for either of two key ECM molecules, collagen II and perlecan, are inactivated. Disruptions in adhesion and ECM functions are also characteristic of various pathologies, including cardiovascular, musculoskeletal, kidney, skin, eye, and bone diseases as well as metastatic cancer, in which cancer cells leave their normal locations and spread throughout the body.

Although many CAMs and adhesion receptors were initially identified and characterized because of their adhesive properties, they also play major roles in signaling, using many of the pathways discussed in Chapters 15 and 16. Figure 20-8 illustrates how integrin adhesion receptors physically and functionally interact, via adapters and signaling molecules, with a broad array of intracellular signaling pathways to influence cell survival, gene transcription, cytoskeletal organization, cell motility, and cell proliferation.

Conversely, changes in the activities of signaling pathways inside cells can influence the structures of CAMs and adhesion receptors — for example, by altering adapter binding to the cytosolic portions of the CAMs — and so modulate their ability to interact with other cells and with the ECM. Thus outside-in and inside-out signaling involve numerous interconnected pathways.

FIGURE 20-8 Integrin adhesion receptor–mediated signaling pathways control diverse cell functions. Binding of integrins to their ligands induces conformational changes in their cytoplasmic domains, directly or indirectly altering their interactions with cytoplasmic proteins (**outside-in signaling**). These cytoplasmic proteins include adapter proteins (e.g., talins, kindlins, paxillin, vinculin) and signaling kinases [Src-family kinases, focal adhesion kinase (FAK), integrin-linked kinase (ILK)] that transmit signals via diverse signaling pathways, thereby influencing cell proliferation, cell survival, cytoskeletal organization, cell migration, and gene transcription. Components of several signaling pathways, some of

which are associated directly with the plasma membrane, are shown in green boxes. Many of the components of the pathways shown here are shared with other cell-surface-activated signaling pathways (e.g., receptor tyrosine kinases shown on the right) and are discussed in Chapters 15 and 16. In turn, intracellular signaling pathways can, via adapter proteins, modify the ability of integrins to bind to their extracellular ligands (**inside-out signaling**). See W. Guo and F. G. Giancotti, 2004, *Nat. Rev. Mol. Cell Biol.* **5**:816–826; and R. O. Hynes, 2002, *Cell* **110**:673–687.

The Evolution of Multifaceted Adhesion Molecules Enabled the Evolution of Diverse Animal Tissues

Cell-cell and cell-matrix adhesions are responsible for the formation, composition, architecture, and function of animal tissues. Not surprisingly, some adhesion molecules are evolutionarily ancient and are among the most highly conserved proteins in multicellular organisms. Some sponges, the most primitive multicellular organisms, express certain CAMs and multi-adhesive ECM molecules whose structures are strikingly similar to those of the corresponding human proteins. The evolution of metazoans has depended on the evolution of diverse adhesion molecules with novel properties and functions whose levels of expression differ in different types of cells. Some CAMs and adhesion receptors (e.g., cadherins, integrins, and Ig-superfamily CAMs such as L1CAM) and some ECM components (e.g., type IV collagen, laminin, nidogen/entactin, and perlecan-like

proteoglycans) are highly conserved because they play crucial roles in many different organisms, whereas other adhesion molecules are less well conserved. Fruit flies, for example, do not have certain types of collagen or the ECM protein fibronectin, which play important roles in mammals.

The diversity of adhesion molecules arises in large part from two phenomena that can generate the numerous closely related proteins, called **isoforms**, that constitute a protein family. In some cases, the different members of a protein family are encoded by multiple genes that arose from a common ancestor by gene duplication and divergent evolution (see the human β-like globin gene cluster in Chapter 7). In other cases, a single gene produces an RNA transcript that can undergo alternative splicing to yield multiple mRNAs, each encoding a distinct protein isoform (see Figure 7-3 and Section 9.2). Both phenomena contribute to the diversity of some protein families, such as the cadherins. Particular isoforms of an adhesive protein are often expressed in some cell types and tissues, but not others.

Cell-Adhesion Molecules Mediate Mechanotransduction

Mechanotransduction is the reciprocal interconversion of a mechanical force — or stimulus — and biochemical processes. These

interconversions underlie a variety of biological activities, such as signaling, regulated gene expression, cell proliferation, cell migration, and interactions among cells and between cells and the ECM. Evolution has produced a wide variety of **mechanosensors** that respond to a mechanical stimulus by changing their shape and activity. Examples include at least one G protein–coupled receptor that appears to respond directly to extracellular shear stress — a force parallel to the surface of the cell, such as that resulting from the flow of blood in a blood vessel — and a variety of ion channel mechanosensors whose opening is sensitive to mechanical stretch of the plasma membrane. These include certain transient receptor potential (TRP) channels as well as Piezo nonselective cation channels (see Chapter 23), which are found in neurons and non-neuronal cells and that respond to a variety of mechanical stimuli, including touch, airway stretch, blood pressure, and shear and osmotic forces.

Mechanotransduction in the context of cell-cell and cell-matrix interactions usually involves a cell-surface adhesion receptor that transmits mechanical force or biochemical information across the plasma membrane and one or more intracellular or extracellular mechanosensors that respond to the mechanical stimulus by changing shape and activity. For example, tension applied across the length of a multidomain mechanosensor protein, such as the ECM protein fibronectin or the integrin adapter protein **talin**, can separate otherwise tightly packed domains, or even literally pull apart (disassemble) individual domains. As a consequence, one or

more binding sites that were otherwise inaccessible (cryptic) are exposed. Figure 20-9 shows examples of domains that are unfolded by mechanical force, exposing cryptic binding sites. The newly accessible binding sites can then recruit binding partners — in some cases after phosphorylation — and alter cellular or extracellular functions. For example, the stretching of fibronectins by integrins induces domain separation and consequently their assembly into fibrils, which is an early step in the assembly of collagen and other molecules into ECM. The mechanical forces in mechanotransduction can be forces generated within a cell, such as myosin-driven movement of actin filaments (Chapter 17), or outside a cell, such as blood flow, movement of adjacent cells, or contraction or expansion of ECM. As we will see later in this chapter, cell-cell and cell-matrix adhesion sites play particularly important roles in mechanotransduction.

FIGURE 20-9 Models of domains in mechanosensor proteins responding to mechanical forces. (a) Hypothetical model of the partial unfolding of a fibronectin type III domain in the ECM molecule fibronectin when that protein is subjected to mechanical force. Mechanical force generated within the cell by actin movement and mechanotransduced via multiple

integrin adhesion receptors bound to the extracellular dimeric fibronectin can partially unfold the fibronectin. The unfolding is thought to expose a putative, previously hidden binding site on fibronectin (blue segment) that has the potential to form β sheets with other fibronectin molecules, recruiting them to form fibronectin fibrils, and helping assemble the ECM. (b) Hypothetical model of the partial unfolding of a domain (the R1 five-helix bundle) in the intracellular integrin adapter protein talin when it is subjected to mechanical stretching force. This force is generated by actin, which can bind to and pull on the C-terminus of talin while talin's N-terminus is bound to the cytoplasmic tail of integrin's β subunit. The unfolding is thought to expose this domain's otherwise cryptic α-helical vinculin binding site (blue). Vinculin, an actin-binding protein, can then bind to the integrin-talin complex via the exposed site and in turn bind to actin, thus promoting the assembly of multiple actin fibers. The assembly of actin fibers indirectly linked by adapters to integrins strengthens integrin-mediated adhesion and helps to build focal adhesions (see Figures 20-14e and 20-40).

KEY CONCEPTS OF SECTION 20.1

Cell-Cell and Cell–Extracellular Matrix Adhesion: An Overview

- Cell-cell and cell–extracellular matrix (ECM) interactions are critical for assembling cells into tissues, controlling cell shape and function, and determining the developmental fate of cells and tissues. Diseases may result from abnormalities in the structures or expression of adhesion molecules.
- Cell-cell adhesion molecules (CAMs, also called *cell-cell adhesion receptors*) mediate direct intercellular cell-cell adhesions (homotypic and heterotypic), and cell-matrix receptors mediate cell attachment to the ECM (see Figure 20-1). These interactions bind cells into tissues and facilitate communication between cells and their environments.
- The cytosolic domains of cell adhesion receptors bind adapter proteins that mediate interaction with cytoskeletal fibers and intracellular signaling proteins.

- The major families of CAMs are the cadherins, lectins, Ig-superfamily CAMs, and integrins (see Figure 20-2). Members of the integrin and IgCAM superfamilies can also function as cell-matrix adhesion receptors.
- Tight cell-cell adhesions entail both trans (adhesive or intercellular) interactions of like (homophilic) or different (heterophilic) CAMs and cis (lateral) oligomerization of CAMs (see Figure 20-3). The combination of trans and cis interactions produces a Velcro-like adhesion between cells.
- The ECM is a dynamic, complex meshwork of proteins and polysaccharides that contributes to the structure and function of a tissue (see Table 20-2). The major classes of ECM molecules are proteoglycans, collagens, and multi-adhesive matrix proteins, such as fibronectin and laminin.
- CAMs and adhesion receptors, together with their cytoplasmic adapter proteins, play major roles in “outside-in” and “inside-out” signaling, facilitating critically important communication between cells and their surroundings.
- The evolution of adhesion molecules with specialized structures and functions permits cells to assemble into diverse classes of tissues with varying functions.
- Mechanotransduction, the interconversion of a mechanical stimulus or force and biochemical processes, is mediated by adhesion receptors and mechanosensors. Adhesion receptors themselves can also be mechanosensors. Mechanotransduction permits cells to respond to mechanical forces from their environments and to exert mechanical forces on their surroundings.

20.2 Cell-Cell and Cell–Extracellular Matrix Junctions and Their Adhesion Molecules

Cells in epithelial and in nonepithelial tissues use many, but not all, of the same cell-cell and cell-matrix adhesion molecules. We begin our detailed discussion of adhesion with epithelia because of their relatively simple organization, as well as their fundamental role in evolution and development. In this section, we focus on regions of the cell surface that contain clusters of adhesion molecules in discrete patches or spots, called *anchoring junctions*, *tight junctions*, and *gap junctions*. Anchoring and tight junctions play critical roles in mediating cell-cell and cell-matrix adhesion, and all three types of junctions mediate intercellular or cell-matrix communication.

Epithelial Cells Have Distinct Apical, Lateral, and Basal Surfaces

Cells that form epithelial tissues are said to be *polarized* because their plasma membranes are organized into discrete regions. Typically, the distinct surfaces of a polarized epithelial cell are called the **apical** (top), **lateral** (side), and **basal** (base or bottom) surfaces (Figure 20-10; see also Figure 20-1). The apical, lateral, and basal surfaces of epithelial cells can exhibit distinctive characteristics. The area of the apical surface is often greatly expanded by the formation of microvilli — small, fingerlike projections (see Chapter 22). A complex set of evolutionarily conserved molecules, called *polarity regulators*, is required to generate the functional and structural asymmetry of epithelial and other cells (see Chapter 22). Adhesion molecules play essential roles in generating and maintaining these distinct surfaces.

FIGURE 20-10 Principal types of epithelia. (a) Simple columnar epithelia consist of elongated cells, including mucus-secreting cells (in the lining of the stomach and cervical tract) and absorptive cells (in the lining of the small intestine). The thin protrusions at the apical surface are microvilli (see Figure 20-11). (b) Simple squamous epithelia, composed of thin cells, line the blood vessels (endothelial cells/endothelium) and many body cavities. (c) Transitional epithelia, composed of several layers of cells with different shapes, line certain cavities subject to expansion and contraction (e.g., the urinary bladder). (d) Stratified squamous (nonkeratinized) epithelia line surfaces such as the mouth and

vagina; these linings resist abrasion and generally do not participate in the absorption or secretion of materials into or out of the cavity. The basal lamina, a thin fibrous network of collagen and other ECM components, supports all epithelia and connects them to the underlying connective tissue.

Epithelia in different body locations have characteristic morphologies and functions (see Figure 20-10; see also Figure 1-4). Stratified (multilayered) epithelia commonly serve as barriers and protective surfaces (e.g., the skin), whereas simple (single-layered) epithelia often selectively move ions and small molecules from one side of the epithelium to the other. For instance, the simple columnar epithelium lining the stomach secretes hydrochloric acid into the lumen; a similar epithelium lining the small intestine transports products of digestion from the lumen of the intestine across the cells into the blood (see Figure 11-30).

In simple columnar epithelia, adhesive interactions between the lateral surfaces hold the cells together in a two-dimensional sheet, whereas those at the basal surface connect the cells to a specialized underlying extracellular matrix called the **basal lamina**. Often the basal and lateral surfaces are similar in composition and are collectively called the **basolateral** surface. The basolateral surfaces of most simple epithelia are usually on the side of the cell closest to the blood vessels, whereas the apical surface is not in stable, direct contact with other cells or the ECM. In animals with closed circulatory systems, blood flows through vessels whose inner lining is composed of flattened epithelial cells called *endothelial cells*. In general, epithelial cells are sessile, in that adhesion molecules firmly and stably attach them to one another and their associated ECM. One especially important mechanism that generates strong, stable adhesions is the concentration of subsets of these molecules into clusters called *cell junctions*.

Three Types of Junctions Mediate Many Cell-Cell and Cell-Matrix Interactions

All epithelial cells in a sheet are connected to one another and to the ECM by specialized junctions. Although hundreds of individual dispersed adhesion

molecule–mediated interactions are sufficient to cause cells to adhere, the clustered groups of adhesion molecules at cell junctions play special roles in imparting strength and rigidity to a tissue, transmitting information between the extracellular and the intracellular space, controlling the passage of ions and molecules across cell layers, and serving as conduits for the movement of ions and molecules from the cytoplasm of one cell to that of its immediate neighbor. Particularly important to epithelia is the formation of junctions that help form tight seals between the cells, allowing the epithelial sheet to serve as a barrier to the flow of molecules from one side of the sheet to the other.

Three major classes of animal-cell junctions are prominent features of simple columnar epithelia (Figure 20-11 and Table 20-3): **anchoring junctions**, **tight junctions**, and **gap junctions**. Anchoring junctions and tight junctions perform the key task of holding the tissue together. As we shall see, tight junctions also control the flow of solutes through the extracellular spaces between the cells forming an epithelial sheet. Tight junctions are found primarily in epithelial cells, whereas anchoring junctions can be seen in both epithelial and nonepithelial cells. Anchoring junctions and tight junctions in epithelia are organized into three parts: (1) adhesive proteins (CAMs, adhesion receptors) in the plasma membrane that connect one cell to another cell on the lateral surfaces or to the ECM on the basal surfaces; (2) adapter proteins, which connect the CAMs or adhesion receptors to cytoskeletal filaments and signaling molecules; and (3) the cytoskeletal filaments themselves.

FIGURE 20-11 Principal types of cell junctions connecting the columnar epithelial cells lining the small intestine. (a) Schematic cutaway drawing of intestinal epithelial cells. The basal surface of the cells rests on a basal lamina, and the apical surface is packed with microvilli that project into the intestinal lumen. Tight junctions, lying just under the microvilli, prevent the diffusion of many substances between the intestinal lumen and internal body fluids (such as the blood) via the extracellular space between cells. Gap junctions allow the movement of small molecules and ions between the cytosols of adjacent cells. The remaining three types of junctions — adherens junctions, desmosomes, and hemidesmosomes — are critical to cell-cell and cell-matrix adhesion and signaling. (b) Electron micrograph of a thin section of epithelial cells in the rat intestine, showing the relative locations of the different junctions.

[Part (b) M. G. Farquhar and G. E. Palade, 1963, *J. Cell Biol.* **17**(2):375–412, Fig. 1; https://doi.org/10.1083/jcb.17.2.375.]

TABLE 20-3 • Cell Junctions

Junction	Adhesion Type	Principal CAMs or Adhesion Receptors	Cytoskeletal Attachment	Intracellular Adapters	Function
Anchoring junctions					
1. Adherens junctions	Cell-cell	Cadherins	Actin filaments	Catenins, vinculin	Shape, tension, signaling, force transmission

2. Desmosomes	Cell-cell	Desmosomal cadherins	Intermediate filaments	Plakoglobin, plakophilins, desmoplakins	Strength, durability, signaling
3. Hemidesmosomes	Cell-matrix	Integrin (α6β4)	Intermediate filaments	Plectin, dystonin/BPAG1	Shape, rigidity, signaling
4. Focal contacts, fibrillar, and 3-D adhesions	Cell-matrix	Integrins	Actin filaments	Talin, kindlin, paxillin, vinculin	Shape, signaling, force transmission, cell movement
Tight junctions	Cell-cell	Occludin, claudins, JAMs	Actin filaments	ZO-1,2,3, PAR3, cingulin	Controlling solute flow, cell polarity, signaling
Gap junctions	Cell-cell	Connexins, innexins, pannexins	Via adapters to other junctions	ZO-1,2,3	Communication, small-molecule transport between cells
Plasmodesmata (plants only)	Cell-cell	Undefined	Actin filaments	NET1A	Communication, molecule transport between cells

Gap junctions permit the rapid diffusion of small, water-soluble molecules between the cytoplasms of adjacent cells. Along with anchoring and tight junctions, gap junctions help a cell communicate with its environment. However, they are structurally very different from anchoring junctions and tight junctions and do not play a key role in strengthening cell-cell and cell-matrix adhesions. Found in both epithelial and nonepithelial cells, gap junctions resemble the distinct cell junctions in plants called *plasmodesmata*, which we discuss in Section 20.6.

Four types of anchoring junctions are present in cells. Two participate in cell-cell adhesion and two participate in cell-matrix adhesion. **Adherens junctions** connect the lateral membranes of adjacent epithelial cells and are usually located near the apical surface, just below the tight junctions (see Figure 20-11). A circumferential

belt of actin and myosin filaments in a complex with the adherens junctions functions as a tension cable that can internally brace the cell and thereby control its shape. Epithelial and some other types of cells, such as smooth muscle and heart cells, are also bound tightly together by **desmosomes**, snap-like points of contact sometimes called *spot desmosomes*. *Hemidesmosomes*, found mainly on the basal surface of epithelial cells, and **focal contacts**, also called **focal adhesions**, anchor an epithelium to components of the underlying ECM, much like nails holding down a carpet. Adherens junctions, desmosomes, and focal adhesions are found in many different types of cells; hemidesmosomes appear to be restricted to epithelial cells.

Bundles of intermediate filaments running parallel to the cell surface or through the cell connect desmosomes and hemidesmosomes, imparting shape and rigidity to the cell, as do actin filaments that connect the cytoskeleton with focal contacts and adherens junctions. The close interaction between these junctions and the cytoskeleton helps transmit shear forces from one region of a cell layer to the epithelium as a whole, providing strength and rigidity to the entire epithelial cell layer. Desmosomes and hemidesmosomes are especially important in maintaining the integrity of skin epithelia. As a consequence, mutations that interfere with hemidesmosomal anchoring in the skin can lead to a condition in which the epithelium becomes detached from its underlying matrix and extracellular fluid accumulates at the basolateral surface, forcing the skin to balloon outward, forming a blister.

Cadherins Mediate Cell-Cell Adhesions in Adherens Junctions and Desmosomes

The primary CAMs in adherens junctions and desmosomes belong to the **cadherin** family of glycoproteins that can contain oligosaccharides that are either *N*-linked (see Chapters 13 and 14) or *O*-linked (described in Figure 20-31 in Section 20.4). In vertebrates, this protein superfamily of more than a hundred members can be grouped into at least six subfamilies, including **classical cadherins**, **clustered protocadherins**, and **desmosomal cadherins**, which we will describe below. The

diversity of cadherins arises from the presence of multiple cadherin genes and alternative RNA splicing. It is not surprising that there are many different types of cadherins in vertebrates; many different types of cells in the widely diverse tissues of these animals use cadherins to mediate adhesion and communication, the detailed requirements for which may differ for different types of cells and tissues. Members of the cadherin superfamily can also control cell morphology, such as the assembly and tight packing of microvilli on the apical surfaces of some epithelial cells (see Figures 20-10a and 20-11a). The brain expresses the largest number of different cadherins, including protocadherins, presumably owing to the necessity of forming many specific cell-cell contacts to help establish its complex wiring pattern. Invertebrates, however, are able to function with fewer than 20 cadherins.

Classical Cadherins

The classical cadherins include E-, N-, and P-cadherins, named for the type of tissue in which they were initially identified (epithelial, neural, and placental, respectively). E- and N-cadherins are the most widely expressed, particularly during early differentiation. Sheets of polarized epithelial cells, such as those that line the small intestine or kidney tubules, contain abundant E-cadherin along their lateral surfaces. Although E-cadherin is concentrated in adherens junctions, it is present throughout the lateral surfaces, where it is thought to link adjacent cell membranes.

The results of experiments with L cells, a line of cultured mouse fibroblasts, demonstrated that E-cadherins preferentially mediate homophilic interactions. L cells express no cadherins and adhere poorly to each other and to other types of cells. When the E-cadherin gene was introduced into L cells, the cells were found to adhere preferentially to other cells expressing E-cadherin (Figure 20-12). These engineered cadherin-expressing L cells formed epithelium-like aggregates with one another and with epithelial cells isolated from lungs. Although most E-cadherins exhibit primarily homophilic binding, some mediate heterophilic interactions.

EXPERIMENTAL FIGURE 20-12 E-cadherin mediates Ca^{2+}-dependent adhesion of L cells. Under standard cell-culture conditions, in the presence of calcium in the extracellular fluid, L cells do not aggregate into sheets (*left*). Introduction of a gene that causes the expression of E-cadherin in these cells results in their aggregation into epithelium-like clumps in the presence of calcium (*center*), but not in its absence (*right*). Bar, 60 μm.

[© C. L. Adams et al., 1998, *J. Cell Biol.* **142**(4):1105–1119, Fig. 1E; https://doi.org/10.1083/jcb.142.4.1105.]

The adhesiveness of cadherins depends on the presence of extracellular Ca^{2+}; it is this property (*c*alcium *a*dhering) that gave rise to their name. For example, the adhesion of L cells expressing E-cadherin is prevented when the cells are bathed in a solution that is low in Ca^{2+} (see Figure 20-12). Some adhesion molecules require some minimal amount of Ca^{2+} in the extracellular fluid to function properly, whereas others, such as IgCAMs, are Ca^{2+} independent.

The role of E-cadherin in adhesion can also be demonstrated by experiments with cultured epithelial cells called *Madin-Darby canine kidney (MDCK)* cells (see Figure 4-3). A green fluorescent protein–labeled form of E-cadherin has been used in these cells to show that clusters of E-cadherin mediate the initial attachment of the cells and the subsequent zippering of the cells into sheets (Figure 20-13). In this experimental system, the addition of an antibody that binds to E-cadherin, preventing its homophilic interactions, blocks the Ca^{2+} - dependent attachment of

MDCK cells to one another and the subsequent formation of intercellular adherens junctions.

EXPERIMENTAL FIGURE 20-13 E-cadherin mediates adhesive connections in cultured MDCK epithelial cells. An E-cadherin gene fused to green fluorescent protein (GFP) was introduced into cultured MDCK cells. The cells were then mixed together in a calcium-containing medium, and the distribution of fluorescent E-cadherin was visualized over time (shown in hours). Clusters of E-cadherin mediate the initial attachment and subsequent zippering up of the epithelial cells and the formation of junctions (bicellular junctions are where two cells join and appear as lines; tricellular junctions are the sites of intersection of three cells).

[© C. L. Adams et al., 1998, *J. Cell Biol.* **142**(4):1105–1119, Fig. 2B; https://doi.org/10.1083/jcb.142.4.1105.]

Each classical cadherin molecule contains a single transmembrane domain, a relatively short C-terminal cytosolic domain, and five extracellular cadherin domains (called *EC1–EC5*) (see Figure 20-2). The extracellular domains are necessary for Ca^{2+} binding and cadherin-mediated cell-cell adhesion. Classical cadherin–mediated adhesion entails both cis lateral (on the same cell) clustering and trans adhesive (intercellular) molecular interactions (see Figures 20-3 and 20-14a–c). The binding of three Ca^{2+} ions at each of the sites located between the cadherin repeats (see Figures 20-2 and 20-14a) stabilizes the elongated and curved structure of the extracellular domain. As we shall see shortly, the curved structure of cadherin's extracellular domain is necessary for the proper molecular complementarity that stabilizes cis and trans binding between cadherin molecules. The cis and trans interactions of cadherins, together with their interactions with cytoplasmic adapter and cytoskeletal molecules, permit the zippering up of cadherins into adhesive arrays. Binding of the

EC1 domain of one cadherin molecule to the EC1 domain of another on the adjacent cell is responsible for trans binding (Figure 20-14a; see also Figure 20-3). Although the dissociation constant (K_d) for EC1–EC1 homophilic binding measured using isolated domains in solution is on the order of $10^{-5} - 10^{-4}$ mol/L (relatively weak, or low-affinity, binding), the multiple low-affinity interactions in arrays of intact cadherin molecules on adjacent cells sum to produce a very tight intercellular adhesion.

FIGURE 20-14 Trans (intercellular) and cis (on the same cell) interactions of classical cadherins in typical adherens junctions and of protocadherins. (a) The exoplasmic cadherin domains [EC1-EC5, see ovals in (b)] of E-cadherins at adherens junctions on adjacent cells are clustered by homophilic cis and trans interactions (see Figure 20-3). The Ca^{2+}-dependent elongated and curved structure of cadherin's extracellular domains is necessary for stable cis and trans interactions (examples highlighted by dashed circles). (b) EC1-EC2 cis interaction. Cis interactions are defined by the binding of an EC1 domain of one cadherin to an EC2 domain of an adjacent cadherin on the same cell. In (b) and (c) the structure of each extracellular cadherin domain is represented using a ribbon

diagram and highlighted by an oval. (c) EC1-EC1 trans interaction: Two views rotated by 90° of the trans binding of an EC1 domain of one cadherin to an EC1 domain of a cadherin on the adjacent cell. Only the EC1 and a portion of the EC2 domains are shown. Note that a small segment of polypeptide at the N-terminus of each of the two EC1 domains [highlighted in yellow (cell 1) and blue (cell 2)] swings out and replaces the equivalent segment from its binding partner (strand swap, dashed oval on the right). The strand swap places the side chain of a tryptophan residue on each of the segments into a binding pocket on the adjacent EC1 domain — an interaction that substantially stabilizes the trans binding. (d) The clustered protocadherins at neuron-to-neuron interfaces form a lattice of cis and trans interactions with their exoplasmic cadherin domains (ovals, EC1-EC6) that differs from that in classical cadherins (part a). Different protocadherin isoforms are represented by different colors (lighter colors expressed by Cell 1, darker colors expressed by Cell 2). The dimeric, homo- (same color) and heterophilic (different colors) cis interactions form between the EC6 domain of one molecule and EC5-EC6 domains of its partner (cis dashed circle). The dimeric, homophilic trans interactions form between the EC1-EC4 domains of one molecule with the EC1-EC4 domains of the same isoform (same color) on the adjacent cell. (e) The cytosolic domains of the classical E-cadherins bind directly or indirectly to multiple adapter proteins (e.g., β-catenin), which both connect the junctions to actin filaments (F-actin) of the cytoskeleton and participate in intracellular signaling pathways. Somewhat different sets of adapter proteins are illustrated in the two cells to emphasize the variety of adapters in adherens junctions. Some of these adapters, such as vinculin and ZO-1, can interact with several different CAMs. See V. Vasioukhin and E. Fuchs, 2001, *Curr. Opin. Cell Biol.* **13**:76–84; and J. Brasch, et al., 2012, *Trends Cell Biol.* **22**:299–310.

[Parts (a–c) Data from O. J. Harrison et al., 2011, *Structure* **19**: 244–256, PDB ID 3q2w. Part (d) Data from J. Brasch et al., 2019, *Nature* **569**: 280–283, PDB ID 6e6b.]

Determination of the structures of the extracellular domains of cadherins, together with analyses of the structures and binding properties of many mutants of the key binding domains, have provided a clear picture of the cis and trans interactions that underlie classical cadherin–mediated cell adhesion. The key features of cadherin cis and trans binding interactions are (1) the calcium-dependent curvature of the five extracellular cadherin domains that permits proper relative orientations of the EC1 and EC2 domains (see Figures 20-2 and 20-14a); (2) for cis interactions, the binding of one side of an EC1 domain to a complementary surface on the EC2 domain of an adjacent molecule on the same membrane (see Figures 20-2 and 20-14a and b); and (3) for trans interactions, the binding of a different surface of the EC1 domain to an EC1 domain from a cadherin molecule on the adjacent cell (Figure 20-14c). The trans EC1–EC1 binding is stabilized when a small segment of the protein at the N-terminus of each of the two EC1 domains swings out and replaces the equivalent segment from its binding partner (strand swap; see Figure 20-14c).

Another group of CAMs, called *clustered protocadherins*, provides an excellent example of how evolution can employ common molecular building blocks — in this case, cadherin domains — for distinct structural and functional purposes. Clustered protocadherins play a role in establishing the complex wiring diagram of neurons in mammalian brains. Multiple protocadherin genes encode 52 different clustered protocadherin proteins (isoforms) in humans (58 in mice). The random combinations of 10–15 different isoforms that are expressed in any individual neuron provide a bar code that helps a neuron distinguish itself from other neurons and thus helps generate neuronal wiring diagrams. The domain architecture of these protocadherins with six extracellular cadherin domains (EC1–EC6) differs from that of classical cadherins with five domains, and the organization of the cis and trans binding (see Figure 20-14d) differs markedly from that of classical cadherins (see Figure 20-14a–c). In clustered protocadherins, cis interactions are mediated by the EC6 domain of one molecule binding to the EC5 and EC6 domains of an adjacent molecule (Figure 20-14d). These cis interactions can be both homophilic and heterophilic, allowing the same or different isoforms to associate with each other into cis dimers [different colors represent different isoforms in part (d)]. In contrast, trans interactions are mediated by strictly homophilic, antiparallel binding of the EC1-EC4-domains (see Figure 20-14d). Trans binding only occurs when the sequences of all four of these EC domains perfectly match those of a corresponding protocadherin isoform on the adjacent cell. The lattices of intermixed protocadherin isoforms that form an interface between the membranes of neurons are responsible for their influence on neuronal wiring.

The cytosolic domains of CAMs have profound effects on the binding properties and functions of these adhesive molecules. For example, the C-terminal cytosolic domain of classical cadherins is linked to the actin cytoskeleton by adapter proteins (Figure 20-14e). These linkages are essential for strong adhesion. Indeed, cadherins together with their adaptor proteins in adherens junctions participate in mechanotransduction; a moderate increase in the mechanical tension at the junctions generated either intracellularly by actin and myosin, or by extracellular forces such as those transferred from adjacent cells or shear force due to blood flow, induces the formation of larger clusters of cadherins and stronger intercellular

adhesion. An important mechanosensor is the adapter protein α-catenin, which is attached to the cytoplasmic domain of cadherin via the protein β-catenin and also binds directly to F-actin (see Figure 20-14e). When the cadherin/β-catenin/α-catenin/F-actin complex is subjected to mechanical stress, the C-terminal actin-binding domain of α-catenin undergoes a conformational change to bind more tightly to the actin. In addition, a tension-induced conformational change in α-catenin's adhesion modulation domain uncovers otherwise cryptic binding sites for additional proteins, including the actin-binding adaptor vinculin. As a consequence, additional F-actin filaments can be recruited (see Figure 20-14e) and these further enlarge and strengthen the adherens junction. We will see vinculin playing a similar role in integrin-mediated adhesion later in this chapter.

Disruption of the interactions between classical cadherins and α-catenin or β-catenin dramatically reduces cadherin-mediated cell-cell adhesion. This disruption occurs spontaneously in tumor cells, which sometimes fail to express α-catenin, and can be induced experimentally by depleting the cytosolic pool of accessible β-catenin. The cytosolic domains of cadherins also interact with other adaptor molecules including p120-catenin, which can influence the stability of the cadherin. Interestingly, β-catenin plays a dual role: it not only mediates cytoskeletal attachment, but also serves as a signaling molecule, translocating to the nucleus and altering gene transcription in the Wnt signaling pathway (see Figure 16-26).

Classical cadherins play a critical role during tissue differentiation. Each classical cadherin has a characteristic tissue distribution. In the course of differentiation, the amounts or types of cell-surface cadherins change, affecting many aspects of cell-cell adhesion, cell migration, and cell division. For instance, the normal reorganization of tissues during morphogenesis is often accompanied by the conversion of nonmotile epithelial cells into motile cells, called *mesenchymal* cells, that are precursors for other tissues. This **epithelial-to-mesenchymal transition (EMT)** is associated with a reduction in the expression of E-cadherin (Figure 20-15a, b). The EMT is also associated with pathology, as in the conversion of epithelial cells into malignant carcinoma cells. For example, certain ductal breast tumors and hereditary diffuse gastric cancer (Figure 20-15c) characteristically involve a loss of E-

cadherin activity. It is well known that animal cell-cell contact can inhibit cell proliferation. During tissue development, once dividing epithelial cells have formed a well-defined, tightly bound epithelium, they have no need for further cell division unless they are damaged or receive a signal to undergo the EMT. It is now clear that one mechanism used to inhibit proliferation of epithelial cells in epithelia is E-cadherin- and catenin-mediated regulation of the Hippo pathway that controls cell proliferation (see Chapter 21).

The firm epithelial cell-cell adhesions mediated by cadherins in adherens junctions permit the formation of a second class of intercellular junctions in epithelia — tight junctions, to which we will turn shortly.

Infection with rhinoviruses (RV) is the most frequent cause of the common cold, and infection with virulent class C rhinoviruses (RV-C) can cause more severe illnesses, including exacerbation of asthma. To enter cells and replicate, RV-C must bind to cell-surface receptors. A cadherin family member called *CDHR3*, which is highly expressed in epithelial cells in the human airway, is a receptor for RV-C. Pathogens such as RV-C often evolve to co-opt proteins that have normal functions in their target (host) tissues. Genetic studies have shown that a naturally occurring mutation in humans that changes a cysteine to tyrosine (C → Y) in the EC5 domain of CDHR3 is associated with increased wheezing illnesses and hospitalizations for childhood asthma. In cultured cells, this C → Y mutation increases the cell-surface expression of CDHR3 and the binding and replication of RV-C. Treatments that disrupt the RV-C/cadherin (CDHR3) interaction have the potential to prevent or treat respiratory diseases caused by RV-C. ■

Desmosomal Cadherins

Desmosomes (Figure 20-16) contain two specialized cadherins, *desmoglein* and *desmocollin*, whose cytosolic domains are distinct from those in the classical cadherins. The cytosolic domains of desmosomal cadherins bind to adapter proteins

such as plakoglobin (similar in structure to β-catenin) and plakophilins, and these bind to a member of the plakin family of adapters, called *desmoplakin*. These adapters form the thick cytoplasmic plaques that are characteristic of desmosomes. The desmoplakins directly mediate plaque binding to intermediate filaments.

FIGURE 20-16 Desmosomes. (a) Model of a desmosome between epithelial cells with attachments to the sides of intermediate filaments. The key CAMs in desmosomes are the desmosomal cadherins desmoglein and desmocollin. Adapter proteins bound to the cytoplasmic domains of these cadherins include plakoglobin, desmoplakins, and plakophilins. See B. M. Gumbiner, 1993, *Neuron* **11**:551–564; L. A. Staehelin and B. E. Hull, 1978, *Sci. Am.* **238**:140; and D. R. Garrod, 1993, *Curr. Opin. Cell Biol.* **5**:30–40. (b) Electron micrograph of a thin section of a desmosome connecting two cultured differentiated human keratinocytes. Bundles of intermediate filaments radiate from the two darkly staining cytoplasmic plaques that line the inner surface of the adjacent plasma membranes. *Inset:* Electron microscopic tomograph of a desmosome linking two human epidermal cells (plasma membranes, pink; desmosomal cadherins, blue; bar, 35 nm).

[Part (b) republished with permission from Nature, from A. Al-Amoudi et al., 2007, "The Molecular Architecture of Cadherins in Native Epidermal Desmosomes," *Nature* **450**(7171): 832–837; permission conveyed through Copyright Clearance Center, Inc.]

The cadherin desmoglein was identified through studies of an unusual but revealing skin disease called *pemphigus vulgaris*, an autoimmune disease. Patients with autoimmune disorders synthesize self-attacking (or "auto") antibodies that bind to a normal body protein. In pemphigus vulgaris, the auto-antibodies disrupt adhesion between epithelial cells, causing blisters of the skin and mucous membranes. The predominant auto-antibodies in patients were shown to be specific for desmoglein; indeed, the addition of such antibodies to normal skin induces the formation of blisters and disruption of cell adhesion. ■

Integrins Mediate Cell-Matrix Adhesions, Including Those in Epithelial-Cell Hemidesmosomes

To be stably anchored to solid tissues and organs, simple columnar epithelial sheets must be firmly attached via their basal surfaces to the underlying ECM (basal lamina). This attachment occurs via adhesion receptors called **integrins** (see Figure 20-2), which are located both within and outside of anchoring junctions called *hemidesmosomes* (see Figure 20-11a). Hemidesmosomes comprise integral membrane proteins linked via cytoplasmic adapter proteins (e.g., plakins) to keratin-based

intermediate filaments. The principal ECM adhesion receptor in epithelial hemidesmosomes is integrin α6β4.

Integrins function as cell-cell and cell-ECM adhesion receptors in a wide variety of epithelial and nonepithelial cells, mediating many cell-matrix and cell-cell interactions (Table 20-4). In vertebrates, at least 24 integrin heterodimers, composed of 18 types of α subunits and 8 types of β subunits in various αβ heterodimeric combinations, are known. A single type of β chain can interact with any one of several different types of α chains, forming distinct integrins that bind different ligands. This phenomenon of *combinatorial diversity* allows a relatively small number of components to serve a large number of distinct functions. Although most cells express several distinct integrins that bind the same or different ligands, many integrins are expressed predominantly in certain types of cells. Not only do many integrins bind more than one ligand, but there are ligands that can bind to any one of several different integrins.

TABLE 20-4 • Selected Vertebrate Integrins

Subunit Composition	Primary Cellular Distribution	Ligands
α1β1	Many types	Mainly collagens
α2β1	Many types	Mainly collagens; also laminins
α3β1	Many types	Laminins
α4β1	Hematopoietic cells	Fibronectin; **VCAM-1**
α5β1	Fibroblasts	Fibronectin
α6β1	Many types	Laminins
αLβ2	T lymphocytes	**ICAM-1, ICAM-2**
αMβ2	Monocytes	Serum proteins (e.g., C3b, fibrinogen, factor X); **ICAM-1**
αIIbβ3	Platelets	Serum proteins (e.g., fibrinogen, von Willebrand factor, vitronectin); fibronectin

α6β4	Epithelial cells	Laminin

NOTE: The integrins are grouped into subfamilies having a common β subunit. Ligands shown in red are CAMs; all others are ECM or serum proteins. Some subunits can have multiple spliced isoforms with different cytosolic domains.

SOURCE: Data from R. O. Hynes, 1992, *Cell* **69**(1):11.

All integrins appear to have evolved from two ancient general subgroups: those that bind proteins containing the tripeptide sequence Arg-Gly-Asp, usually called the **RGD motif** (fibronectin is one such protein), and those that bind laminin. Several integrin α subunits contain a distinctive, inserted domain, the *I-domain*, which can mediate binding of certain integrins to various collagens in the ECM. Some integrins with I-domains are expressed exclusively on leukocytes (white blood cells) and red and white blood cell precursor (hematopoietic) cells. I-domains also recognize CAMs on other cells, including members of the Ig superfamily (e.g., ICAMs, VCAMs), and thus participate in cell-cell adhesion.

Integrins typically exhibit low affinities for their ligands, with dissociation constants (K_d) between 10^{-6} and 10^{-7} mol/L. However, the multiple weak interactions generated by the binding of hundreds or thousands of integrin molecules to their ligands on cells or in the ECM allow a cell to remain firmly anchored to its ligand-expressing target.

Parts of both the α subunit and the β subunit of an integrin molecule contribute to the primary extracellular ligand-binding site (see Figure 20-2). Ligand binding to integrins also requires the simultaneous binding of divalent cations. Like that of other adhesion molecules, the cytosolic region of integrins interacts with adapter proteins, which in turn bind to the cytoskeleton and to intracellular signaling molecules (see Figure 20-8). Most integrins are linked via adapters to the actin cytoskeleton, including two of the integrins that connect the basal surface of epithelial cells to the basal lamina via the ECM molecule laminin. Some integrins, however, interact with intermediate filaments. The cytosolic domain of the β4 chain in the α6β4 integrin in hemidesmosomes (see Figure 20-1), which is much longer

than the cytosolic domains of other integrin β chains, binds to specialized adapter proteins, which in turn interact with keratin-based intermediate filaments (see Table 20-4). Other integrins (e.g., α3β1) are the adhesion receptors in the focal contacts linking the epithelial basal lamina with the actin cytoskeleton (see Figure 20-1).

As we will see, the diversity of integrins and their ECM ligands allows integrins to participate in a wide array of key biological processes, including the inflammatory response and the migration of cells to their correct locations during morphogenesis. The importance of integrins in diverse processes is highlighted by the defects exhibited by knockout mice engineered to have mutations in various integrin subunit genes. These defects include major abnormalities in development, blood vessel formation, leukocyte function, inflammation, bone remodeling, and blood clotting. Despite their differences, all these processes depend on integrin-mediated interactions between the cytoskeleton and either the ECM or CAMs on other cells.

In addition to their adhesion function, integrins can mediate outside-in and inside-out signaling (see Figure 20-8). The engagement of integrins by their extracellular ligands can, through adapter proteins bound to the integrin's cytosolic region, influence the cytoskeleton and intracellular signaling pathways (outside-in signaling). Conversely, intracellular signaling pathways can alter the structure of integrins and consequently their abilities to adhere to their extracellular ligands and mediate cell-cell and cell-matrix interactions (inside-out signaling). We will see a detailed example of integrin-mediated signaling later in this chapter. Integrin-mediated signaling pathways influence processes as diverse as cell survival, cell proliferation, and programmed cell death (see Chapter 21).

Tight Junctions Seal Off Body Cavities and Restrict Diffusion of Membrane Components

For polarized epithelial cells to function as barriers and mediators of selective transport, extracellular fluids surrounding their apical and basolateral membranes must be kept separate. Tight junctions between adjacent epithelial cells are usually

located in a band surrounding the cell just below the apical surface (Figure 20-17; see also Figure 20-11). These specialized junctions form a barrier that seals off body cavities such as the intestinal lumen and separates the blood from the cerebral spinal fluid of the central nervous system (i.e., the blood-brain barrier).

FIGURE 20-17 Tight junctions. (a) Freeze-fracture preparation of tight-junction zone between two intestinal epithelial cells. The fracture plane passes through the plasma membrane of one of the two adjacent cells (see also Figure 20-11). A honeycomb-like network of ridges and grooves below the microvilli constitutes the tight-junction zone. (b) Schematic drawing shows how a tight junction might be formed by the linkage of rows of protein particles in adjacent cells. In the inset micrograph of an ultrathin sectional view of a tight junction, the adjacent cells can be seen in close contact where the rows of proteins interact. See L. A. Staehelin and B. E. Hull, 1978, *Sci. Am.* **238**:140.

[Part (b) republished with permission from Nature, from S. Tsukita, M. Furuse, and M. Itoh, 2001, "Multifunctional Strands in Tight Junctions," *Nat. Rev. Mol. Cell Biol*. **2**(4):285–293; permission conveyed through Copyright Clearance Center, Inc.]

Tight junctions prevent the diffusion of macromolecules and, to varying degrees, small water-soluble molecules and ions across an epithelium via the spaces between cells. They also help establish and maintain the polarity of epithelial cells by preventing the diffusion of membrane proteins and glycolipids between the apical and the basolateral regions of the plasma membrane, ensuring that these regions contain different membrane components. Indeed, the lipid compositions of the apical and basolateral regions of the plasma membrane's exoplasmic leaflet (see Chapter 10) are distinct. Essentially all cell surface glycolipids are restricted to the exoplasmic face of the apical membrane, as are all proteins linked to the membrane by a glycosylphosphatidylinositol (GPI) anchor (see Figure 10-19). In contrast, the apical and basolateral regions of the plasma membrane's cytosolic leaflet have uniform membrane composition in epithelial cells; their lipids and proteins can apparently diffuse laterally from one region of the membrane to the other.

Tight junctions are composed of thin bands of plasma-membrane proteins that completely encircle the cell and are in contact with similar thin bands on adjacent cells. When thin sections of the tight junctions in cells are viewed in an electron microscope, the lateral surfaces of adjacent cells appear to touch each other at intervals and even to fuse in the zone just below the apical surface (see Figure 20-11b). In freeze-fracture preparations, tight junctions appear as an interlocking network of ridges and grooves in the plasma membrane (Figure 20-17a). Very high magnification reveals that rows of protein particles 3–4 nm in diameter form the ridges seen in freeze-fracture micrographs of tight junctions. In the model shown in

Figure 20-17b, the tight junction is formed by a double row of these particles, one row donated by each cell. Treatment of an epithelium with the protease trypsin destroys the tight junctions, supporting the proposal that proteins are essential structural components of these junctions.

There are a number of integral membrane proteins found in tight junctions; two of the best studied are *occludin* and *claudin* (from the Latin *claudere*, "to close"). Each of these proteins has four membrane-spanning α helices (Figure 20-18) and are representative of a group of such cell-surface proteins called *tetraspanins*. The mammalian claudin gene family encodes as many as 27 homologous proteins that exhibit distinct tissue-specific patterns of expression and, as described below, exhibit distinct properties. A group of *junction adhesion molecules (JAMs)* have also been found to contribute to homophilic adhesion and other functions of tight junctions. JAMs and another junctional protein, the *coxsackievirus and adenovirus receptor (CAR)*, contain a single transmembrane α helix and belong to the Ig superfamily of CAMs. The extracellular domains of rows of occludin, claudin, and JAMs in the plasma membrane of one cell apparently form extremely tight links with similar rows of the same proteins in an adjacent cell, creating a tight seal. Ca^{2+}-dependent cadherin-mediated adhesion also plays an important role in tight-junction formation, stability, and function.

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

FIGURE 20-18 Proteins that compose tight junctions. (a) Immunofluorescence localization of occludin (green) and tricellulin (red) in mouse intestinal epithelium. Note that tricellulin is predominantly concentrated in tricellular junctions. (b) The junction adhesion molecule (JAM) has a single transmembrane domain and an extracellular region with two immunoglobulin domains, whereas occludin and claudins contain four transmembrane helices. The transmembrane helices of claudin-15 form a four-helix bundle, and the extracellular loops contain a five-stranded β sheet (seen edgewise in this view) and α helices. These extracellular secondary structures participate in cis interactions that form a single-file row of claudins, which in turn interact via other cis contacts with an adjacent row of claudins in the same membrane of each cell. There are also trans interactions between the rows of claudins in adjacent cells (see also Figure 20-20).

[Part (a) J. Ikenouchi et al., 2005, *J. Cell Biol.* **171**(6):939–945, Fig. 3A; https://doi.org/10.1083/jcb.200510043. Part (b) structure of claudin-15 data from H. Suzuki et al., 2014,

Science **344**:304–307, PDB ID 4p79.]

At the intersection of three cells connected to one another by tight junctions (see Figure 20-13 and Figure 20-18a), two additional transmembrane proteins are incorporated into the tight junctions: *tricellulin*, which has four membrane-spanning helices; and *angulins*, which have a single transmembrane helix and one extracellular immunoglobulin domain and appear to be required for the assembly of tricellulin where the cells intersect. As with tight junctions, there appear to be tension-sensitive proteins that localize at tricellular vertices in at least some adherens junctions.

As is the case for adherens junctions and desmosomes, cytosolic adapter proteins and their connections to the cytoskeleton are critical components of tight junctions and can mediate signaling. For example, when one specific claudin, claudin-6, is engaged in intercellular tight junctions, its cytoplasmic domain can initiate a kinase signaling cascade that results in the activation of nuclear receptors (e.g., the retinoic acid receptor γ and the estrogen receptor α) to control cell behavior (see Chapter 8). Also, the long C-terminal cytosolic segment of occludin binds to PDZ domains in some large, multidomain adapter proteins. **PDZ domains** are about 80 to 90 amino acids long and are found in various cytosolic proteins; they mediate binding to other cytosolic proteins or to the C-termini of particular plasma-membrane proteins. Cytosolic proteins containing a PDZ domain often have more than one of them. In the human genome, there are more than 250 PDZ domains in hundreds of proteins. Proteins with multiple PDZ domains can serve as scaffolds on which to assemble proteins into larger functional complexes. Several multiple-PDZ-domain–containing adapter proteins are associated with tight junctions, including the *zonula occludens (ZO)* proteins ZO-1, ZO-2, and ZO-3, which not only interact with occludin, claudin, and other adapter and signaling proteins but also mediate association with actin fibers. These interactions appear to stabilize the linkage between occludin and claudin molecules that is essential for maintaining the integrity of tight junctions. ZO proteins, which may form phase-separated biomolecular condensates at tight

junctions, can also function as adapters in adherens junctions (see Figure 20-14) and gap junctions.

The role of tight junctions as permeability barriers has been demonstrated in many experiments. For example, in one simple experiment, lanthanum hydroxide (an electron-dense colloid of high molecular weight) is injected into the pancreatic blood vessel of an experimental animal; a few minutes later, the pancreatic epithelial acinar cells are fixed and prepared for microscopy. As shown in Figure 20-19, the lanthanum hydroxide diffuses from the blood into the space that separates the lateral surfaces of adjacent acinar cells, but it cannot penetrate past the tight junction.

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

EXPERIMENTAL FIGURE 20-19 Tight junctions prevent passage of large molecules through extracellular spaces between epithelial cells. Tight junctions in the pancreas are impermeable to the

large water-soluble colloid lanthanum hydroxide (dark stain) administered from the basolateral side of the epithelium.

[From D. S. Friend and N. B. Gilula, 1972, *J. Cell Biol.* **53**(3):758–776.]

As a consequence of tight junctions, many nutrients cannot move across an epithelium between cells; instead, their transport is achieved in large part through the **transcellular pathway** via specific membrane-bound transport proteins (Figure 20-20a; see also Figure 11-30). The barrier to diffusion provided by tight junctions, however, is not absolute; some can exhibit size- and ion-selective permeability, depending on the type of claudins incorporated into the tight junction. For some, but not all, claudins the intercellular trans association of their closely packed extracellular domains results in the formation of paracellular channels (pores) (Figure 20-20b). Thus certain small molecules and ions can move from one side of the epithelium to the other through the **paracellular pathway** (see Figure 20-20). The importance of selective permeability is highlighted by the evolutionary conservation of the molecules that establish it and the diseases that arise when it is disrupted. For example, murine embryos cannot develop properly if selective permeability is disrupted because proper fluid balance on the two sides of epithelia cannot be maintained. Similarly, the kidneys depend on proper tight-junction permeability to establish the ion gradients necessary for normal regulation of body fluids and waste removal. Owing at least in part to the varying properties of the different types of claudin molecules located in different tight junctions, the permeability of the tight junctions to ions, small molecules, and water varies enormously among different epithelial tissues.

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

FIGURE 20-20 Transcellular and paracellular pathways of transepithelial transport. (a) Transcellular transport requires the cellular uptake of molecules on one side of the cell and subsequent release on the opposite side by mechanisms for crossing membranes (see Chapter 11). In paracellular transport molecules move extracellularly through channels in the tight junctions, whose permeability to small molecules and ions depends on the composition of the junctional components (mainly claudins) and the physiological state of the epithelial cells. A cross-sectional plane through the tight junction linking the right-most two cells is indicated by dashed lines. Part (b) shows a perpendicular view of this plane

(90 ° rotation). (b) A computational model of claudin-15 in a tight junction. No other tight-junctional proteins are included in this model. This perpendicular view of the cross-sectional plane illustrated in part (a) shows the transmembrane helices of claudin-15 molecules spanning the tight junctional membranes. In each of the two cells, there are adjacent, single-file rows of claudins (orange and blue) that form trans intercellular contacts with the rows of claudins in the adjacent cell. Extracellular channels that are oriented perpendicular to this cross-sectional plane (outlined by gray circles) are formed by the extracellular domains of claudin-15. These channels permit the paracellular movement of small molecules and ions across the epithelium. There are negatively charged side chains of aspartic acid residues that line the channels and appear to contribute to the cation specificity of claudin-15-dependent channels.

[Part (a) Data from S. Tsukita et al., 2001, *Nat. Rev. Mol. Cell Biol.* **2**:285. Part (b) Information from P. Samanta et al., 2018, *J. Gen. Physiol.* **150**:949–968.]

The permeability of tight junctions can be altered by intracellular signaling pathways, especially G protein and cyclic AMP–coupled pathways (see Chapter 15). The regulation of tight-junction permeability is often studied by measuring ion flux (electrical resistance, called *transepithelial resistance*) or the movement of radioactive or fluorescent molecules across monolayers of MDCK or other epithelial cells.

The importance of paracellular transport is apparent in several human diseases. In hereditary hypomagnesemia, a defect in the *claudin16* gene prevents the normal paracellular flow of magnesium in the kidney. This defect results in an abnormally low blood level of magnesium, which can lead to convulsions. Furthermore, a mutation in the *claudin14* gene causes hereditary deafness, apparently by altering transport around hair-cell epithelia in the cochlea of the inner ear.

Some pathogens have evolved to exploit the molecules in tight junctions. Some use junctional proteins as co-receptors to attach to cells prior to infecting them (e.g., hepatitis C virus uses claudin-1 and occludin, together with two other co-receptors, to enter liver cells). Others break down the tight-junction barrier and cross epithelia via paracellular movement, and still others produce toxins that alter barrier function. For example, toxins produced by *Vibrio cholerae*, the enteric bacterium that causes cholera, alter the permeability barrier of the intestinal epithelium by altering the composition or activity of tight junctions. *Vibrio cholerae* also releases a protease that disrupts tight junctions by degrading the extracellular domain of occludin.

Other bacterial toxins can affect the ion-pumping activity of membrane transport proteins in intestinal epithelial cells. Toxin-induced changes in tight-junction permeability (increased paracellular transport) and in protein-mediated ion pumping (increased transcellular transport) can result in massive losses of internal body ions and water into the gastrointestinal tract, which in turn leads to diarrhea and potentially lethal dehydration (see Chapter 11). ■

It is clear that tight junctions are important for maintaining tissue integrity and function. Thus these junctions should and can respond to dynamic changes in epithelia, for example, when they are subjected to either external forces (such as stretching of the bladder by filling with urine) or internal forces (actin-myosin-induced changes in tension). It is clear that when there are changes in the mechanical forces at the tight junction there are coordinated changes in the composition of junctional adaptor proteins and paracellular permeability. The molecular mechanisms underlying mechanotransduction at tight junctions are not as well understood as those at adherens junctions, with some studies suggesting that ZO-1 may serve as a mechanosensor.

Gap Junctions Composed of Connexins Allow Small Molecules to Pass Directly Between the Cytosols of Adjacent Cells

Early electron micrographs of tissues revealed sites of cell-cell contact with a characteristic intercellular gap (Figure 20-21a). This feature, which was found in virtually all animal cells that contact other cells, prompted early morphologists to call these regions gap junctions. In retrospect, the most important feature of these junctions is not the 2–4 nm gap itself, but a well-defined set of cylindrical particles that cross the gap and compose pores connecting the cytosols of adjacent cells (Figure 20-21b, c). As we will see in Section 20.6, plant cells also assemble pores that connect the cytosols of adjacent cells, but those channels, called *plasmodesmata*, differ considerably in structure from gap junctions.

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

FIGURE 20-21 Gap junctions. (a) In this thin section through a gap junction connecting two mouse liver cells, the two plasma membranes are closely associated for a distance of several hundred nanometers, separated by a gap of 2–3 nm. (b) Numerous roughly hexagonal particles are visible in this perpendicular view of the cytosolic face of a region of plasma membrane enriched in gap junctions. Each hexagonal particle aligns with a similar particle on an adjacent cell, forming a channel connecting the two cells. (c) Schematic model of a gap junction connecting two plasma membranes. Both membranes contain connexon hemichannels, cylinders of six dumbbell-shaped connexin molecules. Two connexons join in the gap between the cells to form a gap-junction channel, 1.4–2.0 nm in diameter, that connects the cytosols of the two cells. (d) Structure of recombinant human Cx26 gap junction as determined by x-ray crystallography (3.5-Å resolution). *Left:* Space-filling model of a side view of the complete structure of two attached connexons oriented as in part (c). Each of the six connexins that comprise a connexon has four transmembrane helices and is shown in a distinct color. The structures of the loops connecting the transmembrane helices are not well defined and not shown. *Right:* View from the cytosol perpendicular to the membrane bilayers, looking down on the connexon with its central pore. The diameter of the pore's channel is ~14 Å, and it is lined by

many polar/charged amino acids. See S. Nakagawa, S. Maeda, and T. Tsukihara, 2010, *Curr. Opin. Struct. Biol.* **20**(4):423–430.

[Part (a) courtesy of Daniel Goodenough. Part (b) D. L. Caspar et al., 1977, **74**:605–628, Fig. 2b; https://doi.org/10:1083/jcb.74.2.605. Part (c) Data from L. A. Staehelin and B. E. Hull, 1978, *Sci. Am.* **238**:140. Part (d) Data from S. Maeda et al., 2009, *Nature* **458**:597–602, PDB ID 2zw3.]

In many animal tissues, anywhere from a few to thousands of gap-junction particles cluster together in patches (e.g., along the lateral surfaces of epithelial cells; see Figure 20-11). When the plasma membrane is purified and then sheared into small fragments, some pieces mainly containing patches of gap junctions are generated. Owing to their relatively high protein content, these fragments have a higher density than the bulk of the plasma membrane and can be purified by equilibrium density-gradient centrifugation (see Figure 4-37). When these preparations are viewed perpendicular to the membrane, the gap junctions appear as arrays of hexagonal particles that enclose water-filled channels (see Figure 20-21b).

The effective pore size of gap junctions can be measured by injecting a cell with a fluorescent dye covalently linked to membrane bilayer–impermeable molecules of various sizes and observing with a fluorescence microscope whether the dye passes into neighboring cells. Gap junctions between mammalian cells permit the passage of molecules as large as 1.2 nm in diameter. In insects, these junctions are permeable to molecules as large as 2 nm in diameter. Generally speaking, molecules smaller than 1200 Da pass freely and those larger than 2000 Da do not pass; the passage of intermediate-sized molecules is variable and limited. Thus ions, many low-molecular-weight precursors of cellular macromolecules, products of intermediary metabolism, and small intracellular signaling molecules can pass from cell to cell through gap junctions.

In neural tissue, some neurons are connected by gap junctions through which ions pass rapidly, thereby allowing very rapid transmission of electrical signals. Impulse transmission through these connections, called *electrical synapses*, is almost a thousand times as rapid as at chemical synapses (see Chapter 23). Gap junctions are also present in many non-neural tissues, where they help to integrate the electrical

and metabolic activities of many cells. In the heart, for instance, gap junctions rapidly pass ionic signals among cardiac muscle cells, which are tightly bound together via desmosomes. Thus gap junctions contribute to the electrically stimulated coordinate contraction of cardiac muscle cells during a heartbeat. As discussed in Chapter 15, some extracellular hormonal signals induce the production or release of small intracellular signaling molecules called *second messengers* (e.g., cyclic AMP, IP_3, and Ca^{2+}) that regulate cellular metabolism. Because many second messengers can be transferred between cells through gap junctions, hormonal stimulation of one cell has the potential of triggering a coordinated response by that cell as well as many of its neighbors. Such gap-junction-mediated signaling plays an important role, for example, in the secretion of digestive enzymes by the pancreas and in the coordinated muscular contractile waves (peristalsis) in the intestine. Another vivid example of gap-junction-mediated transport is the phenomenon of *metabolic coupling*, or *metabolic cooperation*, in which a cell transfers nutrients or intermediary metabolites to a neighboring cell that is itself unable to synthesize them. Gap junctions play critical roles in the development of egg precursors (oocytes) in the ovaries by mediating the movement of both metabolites and signaling molecules, such as cyclic GMP, between an oocyte and its surrounding granulosa cells, as well as between neighboring granulosa cells.

A current model of the structure of the gap junction is shown in Figure 20-21c–d. Vertebrate gap junctions are composed of **connexins**, a family of structurally related transmembrane proteins with molecular weights between 26,000 and 60,000. Each vertebrate hexagonal particle consists of 12 noncovalently associated connexin molecules: six form a cylindrical hemichannel, called a *connexon*, in one plasma membrane that is joined to a connexon in the adjacent cell membrane, forming a continuous aqueous channel (diameter ~14 Å) between the cells. Each individual connexin molecule has four membrane-spanning α helices with a topology similar to that of claudin (see Figure 20-18), resulting in 24 transmembrane α helices in each connexon hemichannel.

A completely different family of proteins, the *innexins*, forms the gap junctions in invertebrates. A third family of innexin-like proteins, called *pannexins*, has been found in both vertebrates and invertebrates. Pannexins form hexamer hemichannels (pannexons) whose opening can be regulated by changes in membrane potential or mechanical stress. When open, pannexons permit direct exchange of small molecules (such as ATP) and ions between the intracellular and extracellular spaces. Pannexons are thought to play key roles in release of ATP from cells into the extracellular space. Extracellular ATP (as well as ADP and AMP) can function as an intercellular messenger or transmitter by binding to and activating the cell-surface purinergic receptors P1, P2X, or P2Y on target cells.

There are 21 different connexin genes in humans, and different sets of connexins are expressed in different cell types. The existence of this diversity, together with the generation of mutant mice with inactivating mutations in connexin genes, has highlighted the importance of connexins in a wide variety of cellular systems. Some cells express a single connexin that forms homotypic connexons. Most cells, however, express at least two connexins; these different proteins can assemble into heteromeric connexons, which in turn form heterotypic gap-junction channels. Diversity in channel composition leads to differences in channel permeability. For example, channels made from a 43-kDa connexin isoform, Cx43 — the most ubiquitously expressed connexin — are more than a hundred times as permeable to ADP and ATP as those made from Cx32 (32 kDa).

The permeability of gap junctions is regulated by post-translational modification of connexins (e.g., phosphorylation) and is sensitive to changes in environmental conditions such as intracellular pH and Ca^{2+} concentration, membrane potential, and the intercellular potential between adjacent interconnected cells ("voltage gating"). The N-termini of connexins appear to be especially important in the gating mechanism. Thus, as is the case for many ion channels (see Chapter 11), the channel in some gap junctions can be either opened or closed. One example of the physiological regulation of gap junctions occurs during mammalian childbirth. The smooth muscle cells in the mammalian uterus must contract strongly and synchronously during labor to expel the fetus. To facilitate this coordinated activity,

immediately before and during labor there is an approximately five- to tenfold increase in the amount of the major connexin in these cells, Cx43, and an increase in the number and size of gap junctions, which is reversed rapidly postpartum (following childbirth).

The assembly of connexins, their trafficking within cells, and the formation of functional gap junctions apparently depend on N-cadherin and its associated adapter proteins (e.g., α- and β-catenins, ZO-1, and ZO-2) as well as desmosomal proteins (plakoglobin, desmoplakin, and plakophilin-2). PDZ domains in ZO-1 and ZO-2 bind to the C-terminus of Cx43 and mediate its interaction with catenins and N-cadherin. The relevance of these relationships is particularly evident in the heart, which depends on gap junctions for rapid coordinated electrical coupling and on adjacent adherens junctions and desmosomes for mechanical coupling between cardiomyocytes to achieve the intercellular integration of electrical activity and movement required for normal cardiac function. It is noteworthy that ZO-1 serves as an adapter for adherens (see Figure 20-14), tight, and gap junctions, suggesting that this and other adapters can help integrate the formation and functions of these diverse junctions.

Mutations in connexin genes cause at least eight human diseases, including neurosensory deafness (Cx26 and Cx31), cataracts or heart malformations (Cx43, Cx46, and Cx50), and the X-linked form of Charcot-Marie-Tooth disease (Cx32), which is marked by progressive degeneration of peripheral nerves. ■

Tunneling Nanotubes Can Mediate Metabolic Coupling and Transfer Organelles Between Animal Cells

Tunneling nanotubes can serve as an alternative to gap junctions for moving molecules between cells. Tunneling nanotubes are tubelike projections of the plasma membrane that form a continuous channel connecting the cytosols of animal

cells (Figure 20-22) and can transfer chemical and electrical signals between cells in a manner analogous to structures in plants called *plasmodesmata* (described in Section 20.6). Tunneling nanotubes are typically unbranched, straight tubes and can have a wide variety of diameters (50–300 nm) and lengths (extending between cells from $<10\ \mu m$ to $>100\ \mu m$, they can be longer than several cell diameters). All tunneling nanotubes have actin filaments passing through the central channel, and in some types of cells they also contain microtubules. Remarkably, functional mitochondria can travel between cells by passing through tunneling nanotubes in cell culture (see Figure 20-22) and in vivo, thereby rescuing receiving cells that have mitochondrial defects or deficiencies. Thus the concept of metabolic coupling described for gap junctions can be extended to include the movement of small molecules and organelles through tunneling nanotubes. Pathogens may also use tunneling nanotubes to spread between cells.

EXPERIMENTAL FIGURE 20-22 Microscopic visualization of a tunneling nanotube and mitochondria in cultured human cells. (a) Cultured human retinal pigment epithelial cells (ARPE-19 cell line) were incubated with a fluorescent dye (JC-1) that specifically stains mitochondria and then examined by a combination of conventional bright-field microscopy (see Chapter 4) to visualize the cells and fluorescence microscopy to visualize mitochondria (green intracellular fluorescence). A typical tunneling nanotube can be seen connecting cells 1 and 2. Inset (b) shows a higher magnification of the bright-field-only image with two bulges in the tunneling nanotube highlighted by dashed circles. Inset (c) shows a higher magnification of the same region of the combination image indicating two likely mitochondria within the tunneling nanotube at the positions of those bulges.

KEY CONCEPTS OF SECTION 20.2

Cell-Cell and Cell–Extracellular Matrix Junctions and Their Adhesion Molecules

- Epithelial cells have distinct apical, basal, and lateral surfaces. Microvilli projecting from the apical surfaces of many epithelial cells considerably expand the cells' surface areas.
- Three major classes of cell junctions — anchoring junctions, tight junctions, and gap junctions — assemble epithelial cells into sheets and mediate communication between them (see Figures 20-1 and 20-11). Anchoring junctions can be further subdivided into adherens junctions, focal contacts, desmosomes, and hemidesmosomes.
- Adherens junctions and desmosomes are cadherin-containing anchoring junctions that bind the membranes of adjacent cells, giving strength and rigidity to the entire tissue.
- Cadherins are cell-adhesion molecules (CAMs) responsible for Ca^{2+}-dependent interactions among cells in epithelial and other tissues. They promote strong cell-cell adhesion by mediating both lateral (cis) and adhesive intercellular (trans) interactions.
- Adapter proteins that bind to the cytosolic domain of cadherins and other cell-cell and cell matrix adhesion receptors mediate the association of cytoskeletal and signaling molecules with the plasma membrane (see Figures 20-8 and 20-14). Strong cell-cell adhesion depends on the linkage of the interacting adhesion receptors to the cytoskeleton.
- Hemidesmosomes are integrin-containing anchoring junctions that attach cells to elements of the underlying extracellular matrix.
- Integrins are a large family of αβ heterodimeric cell-surface proteins that mediate both cell-cell and cell-matrix adhesions and inside-out and outside-in signaling in numerous tissues.
- Tight junctions block the diffusion of proteins and some lipids in the plane of the plasma membrane, contributing to the polarity of epithelial cells. They also limit and regulate the extracellular (paracellular) flow of water and solutes from one side of the epithelium to the other (see Figure 20-20). Two key integral membrane proteins found in tight junctions are occludin and claudin.
- Gap junctions are constructed of multiple copies of connexin proteins, which are assembled into a transmembrane channel that connects the cytosols of two adjacent cells (see Figure 20-21). Small molecules and ions can pass through gap junctions, permitting metabolic and electrical coupling of adjacent cells.
- Tunneling nanotubes are tubelike projections of plasma membranes that form a continuous channel connecting the cytosols of nearby animal cells (see Figure 20-22).

20.3 The Extracellular Matrix I: The Basal Lamina

In animals, the extracellular matrix (ECM) has multiple functions (see Table 20-2). The ECM helps organize cells into tissues and coordinates their cellular functions by activating intracellular signaling pathways that control cell growth, proliferation, and gene expression. The ECM can directly influence cell and tissue structure and function. In addition, it can serve as a repository for inactive or inaccessible signaling molecules (e.g., growth factors) that are released to function when the ECM is disassembled or remodeled by hydrolyases, such as proteases. Indeed, hydrolyzed fragments of ECM macromolecules can themselves have independent biological activity. The ensemble of proteins that compose the ECM itself and associated proteins that covalently modify (e.g., chemically cross-link, phosphorylate, cleave), bind to, or otherwise regulate the composition and structure of the ECM is called the *matrisome*. Proteomic (Chapter 3) and genomic analyses suggest that there are approximately 1030 and 1110 genes that encode the human and mouse matrisomes, respectively. Dysfunction of matrisome components can cause a wide variety of diseases that affect many different tissues and organs. It is noteworthy that there are ECM components, as well as extracellular domains of plasma-membrane proteins, that are phosphorylated on serine, threonine, or tyrosine side chains. Kinases that are present in the luminal compartments

of the secretory pathway and some that are apparently secreted into the extracellular space catalyze these phosphorylations.

Many functions of the ECM and, indeed, some features of the assembly of the ECM require transmembrane adhesion receptors, including the integrins, that bind directly to ECM components and that also interact, through adapter proteins, with the cytoskeleton. Adhesion receptors bind to three types of molecules abundant in the ECM of all tissues (see Table 20-1):

- **Proteoglycans**, a group of glycoproteins that cushion cells and bind a wide variety of extracellular and cell-surface molecules
- **Collagen** fibers, which provide structural integrity, mechanical strength, and resilience
- Soluble **multi-adhesive matrix proteins**, such as laminin and fibronectin, which bind to and cross-link adhesion receptors and other ECM components

We begin our description of the structures and functions of these major ECM components in the context of the basal lamina: the specialized sheet of ECM that plays a particularly important role in determining the overall architecture and function of epithelial tissues. In the following section, we discuss the ECM molecules commonly found in nonepithelial tissues, including connective tissue.

The Basal Lamina Provides a Foundation for Assembly of Cells into Tissues

In animals, most organized groups of cells in epithelial and nonepithelial tissues are underlain or surrounded by the basal lamina, a sheet-like meshwork of ECM components usually no more than 60–120 nm thick (Figure 20-23). The basal lamina is structured differently in different tissues. In columnar and other epithelia such as intestinal lining and skin, it is a foundation on which only one surface of the cells rests. In other tissues, such as muscle or fat, the basal lamina surrounds each cell. Basal laminae play important roles in regeneration after tissue damage and in embryonic development. For instance, the basal lamina helps four- and eight-celled embryos adhere together in a ball (see Figures 22-2 and 22-3). In the development of the nervous system, neurons migrate along ECM pathways that contain basal laminal components. In higher animals, two distinct basal laminae are employed to form a tight barrier that limits diffusion of molecules between the blood and the brain (blood-brain barrier), and in the kidney, a specialized basal lamina serves as a selectively permeable blood filter. In muscle, the basal lamina helps protect the cell membranes from damage during contraction and relaxation. Thus the basal lamina is important for organizing cells into tissues and distinct compartments, repairing tissues, forming permeability barriers, and guiding migrating cells

during development. It is therefore not surprising that its components have been highly conserved throughout evolution.

FIGURE 20-23 A basal lamina separates epithelial cells and some other cells from connective tissue. (a) Transmission electron micrograph of a thin section of cells (*top*) and underlying connective tissue (*bottom*). The electron-dense layer of the basal lamina can be seen to follow the undulations of the basal surfaces of the cells. (b) Electron micrograph of a quick-freeze deep-etch preparation of skeletal muscle, showing the plasma membrane, basal lamina, and surrounding connective-tissue collagen fibers. In this preparation, the basal lamina is revealed as a meshwork of filamentous proteins that associates with the plasma membrane and the thicker collagen fibers of the connective tissue.

Most of the ECM components in the basal lamina are synthesized by the cells that rest on it. Four ubiquitous protein components, each of which comprises multiple distinct repeating domains, are found in basal laminae (Figure 20-24):

- *Type IV collagen*, trimeric molecules with both rodlike and globular domains that form a two-dimensional network
- *Laminins*, a family of multi-adhesive, cross-shaped proteins that form a fibrous two-dimensional network with type IV collagen and that also bind to integrins and other adhesion receptors
- *Perlecan*, a large proteoglycan whose protein contains multiple copies of seven different structural domains (total of 48 domains) and which binds to and cross-links many ECM components and cell-surface molecules

- *Nidogen* (also called *entactin*), a rodlike molecule that cross-links type IV collagen, perlecan, and laminin, which helps incorporate other components into the ECM and also stabilizes basal laminae

FIGURE 20-24 Major protein components of the basal lamina. Type IV collagen and laminin each form two-dimensional networks (see Figures 20-25 and 20-27), which are cross-linked by nidogen/entactin, perlecan, and laminin molecules, and which interact via laminins with the plasma membranes of adjacent cells.

Other ECM molecules, such as members of the evolutionarily ancient family of glycoproteins called *fibulins*, are incorporated into various basal laminae, depending on the tissue and the particular functional requirements of the basal lamina.

As depicted in Figure 20-1, one side of the basal lamina is linked to cells by adhesion receptors, including integrins in hemidesmosomes, which bind to laminin in the basal lamina. The other side of the basal lamina is anchored to the adjacent connective tissue by a layer of collagen fibers embedded in a proteoglycan-rich

matrix. In stratified squamous epithelia (e.g., skin; see Figure 20-10d), this linkage between the dermis and epidermis is mediated by anchoring fibrils of type VII collagen. Loss-of-function mutations in the gene encoding type VII collagen results in the rare and debilitating blistering disease called *dystrophic epidermolysis bullosa*. Together, the basal lamina and the anchoring collagen fibrils form the structure called the *basement membrane*.

Laminin, a Multi-Adhesive Matrix Protein, Helps Cross-Link Components of the Basal Lamina

Laminin, the principal multi-adhesive matrix protein in basal laminae, is a heterotrimeric protein comprising α, β, and γ chains. At least 16 laminin isoforms in vertebrates are assembled from 5 α, 3 β, and 3 γ chains, with each chain numbered to reflect the chain composition: laminin-111 (α1β1γ1) or laminin-511 (α5β1γ1). Each laminin isoform exhibits a distinctive pattern of tissue- and developmental stage–specific expression. As shown in Figure 20-25, many laminins are large, cross-shaped proteins (molecular weight of about 820,000), although some are Y- or rod-shaped. Globular domains at the N-terminus of each subunit bind to one another and thus mediate the self-assembly of laminins into mesh-like networks. Five globular *LG domains* at the C-terminus of the laminin α subunit mediate Ca^{2+}-dependent binding to cell-surface laminin receptors,

including certain integrins (see Table 20-4) as well as sulfated glycolipids, syndecan, and dystroglycan, which will be described further in Section 20.4. Some of these interactions are via negatively charged carbohydrates on the receptors. LG domains are found in a wide variety of other proteins and can mediate binding to steroids and proteins as well as carbohydrates. Laminin is the principal basal laminal ligand of integrins.

FIGURE 20-25 Laminin is a heterotrimeric multi-adhesive matrix protein found in all basal laminae. (a) Schematic model of cross-shaped laminin molecule showing the general shape, location of globular domains, and coiled-

coil region in which laminin's three chains are covalently linked by several disulfide bonds. Different regions of laminin bind to adhesion receptors and various matrix components (indicated by arrows and brackets). *Right:* Laminins assemble into a lattice via interactions between their N-terminal globular domains. Sheet-Forming Type IV Collagen Is a Major Structural Component of the Basal Lamina

Type IV collagen is, together with laminin, a principal structural component of all basal laminae and can bind to adhesion receptors, including some integrins. Collagen IV is one of at least 28 types of collagen in humans that participate in the formation of distinct ECMs in various tissues (Table 20-5). There are also at least 20 additional collagen-like proteins (such as host defense collagens) in the human proteome. Although collagen isoforms differ in certain

structural features and in their tissue distribution, all collagens are trimeric proteins made from three polypeptides, each encoded by one of at least 43 genes in humans, usually called *collagen α chains*. The three α chains in a collagen molecule can be identical (forming a homotrimer) or different (forming a heterotrimer). All or parts of the three-stranded collagen molecule can twist together into a special triple helix called a *collagenous* triple helix. When there is more than one triple-helical segment, these segments are joined by nonhelical regions of the protein, as we will see shortly for type IV collagen. Within a helical segment, each of the three α chains twists into a left-handed helix, and the three chains then wrap around one another to form a right-handed triple helix (Figure 20-26).

TABLE 20-5 • Selected Collagens

Type	Molecule Composition	Structural Features	Representative Tissues
Fibrillar Collagens			
I	$[\alpha 1(\mathrm{I})]_2[\alpha 2(\mathrm{I})]$	300-nm-long fibrils	Skin, tendon, bone, ligaments, dentin, interstitial tissues
II	$[\alpha 1(\mathrm{II})]_3$	300-nm-long fibrils	Cartilage, vitreous humor
III	$[\alpha 1(\mathrm{III})]_3$	300-nm-long fibrils; often with type I	Skin, muscle, blood vessels

V	$[\alpha 1(\mathrm{V})]_2[\alpha 2(\mathrm{V})]$, $[\alpha 1(\mathrm{V})]_3$	390-nm-long fibrils with globular N-terminal extension; often with type I	Cornea, teeth, bone, placenta, skin, smooth muscle
Fibril-Associated Collagens			
VI	$[\alpha 1(\mathrm{VI})][\alpha 2(\mathrm{VI})][\alpha 3(\mathrm{VI})]$	Lateral association with type I; periodic globular domains	Most interstitial tissues
IX	$[\alpha 1(\mathrm{IX})][\alpha 2(\mathrm{IX})][\alpha 3(\mathrm{IX})]$	Lateral association with type II; N-terminal globular domain; bound GAG	Cartilage, vitreous humor
Sheet-Forming and Anchoring Collagens			
IV	$[\alpha 1(\mathrm{IV})]_2[\alpha 2(\mathrm{IV})]$	Two-dimensional network	All basal laminae
VII	$[\alpha 1(\mathrm{VII})]_3$	Long fibrils	Below basal lamina of the skin
XV	$[\alpha 1(\mathrm{XV})]_3$	Core protein of chondroitin sulfate proteoglycan	Widespread; near basal lamina in muscle
Transmembrane Collagens			
XIII	$[\alpha 1(\mathrm{XIII})]_3$	Integral membrane protein	Hemidesmosomes in skin
XVII	$[\alpha 1(\mathrm{XVII})]_3$	Integral membrane protein	Hemidesmosomes in skin

Host Defense Collagens

Collectins	Oligomers of triple helix; lectin domains	Blood, alveolar space
C1q	Oligomers of triple helix	Blood (complement)
Class A scavenger receptors	Homotrimeric membrane proteins	Macrophages

SOURCE: Data from K. Kühn, 1987, in R. Mayne and R. E. Burgeson, eds., *Structure and Function of Collagen Types*, Academic Press, p. 2; M. Van Der Rest and R. Garrone, 1991, *FASEB J.* **5**:2814.

The collagen triple helix can form because of an unusual abundance of three amino acids in the α chains: glycine, proline, and a modified form of proline called *hydroxyproline* (see Figure 2-15). They make up the characteristic repeating sequence motif Gly-X-Y, where X and Y can be any amino acid but are often proline in position X and hydroxyproline in position Y, and less often lysine and hydroxylysine. Glycine is essential because its small side chain, a hydrogen atom, is the only one that can fit into the crowded center of the three-stranded helix (see Figure 20-26b). Hydrogen bonds help hold the three chains together. Although the rigid peptidyl-proline and peptidyl-hydroxyproline linkages are not compatible with formation of a classic single-stranded α helix, they stabilize the distinctive collagenous triple helix. The hydroxyl group in

hydroxyproline in the Y position helps hold its ring in a conformation that stabilizes the three-stranded helix.

FIGURE 20-26 The collagen triple helix. (a) *Left:* Side view of the crystal structure of a polypeptide fragment whose sequence is based on repeating sets of three amino acids, Gly-X-Y, characteristic of collagen α chains. *Center:* Each chain is twisted into a left-handed helix, and three chains wrap around one another to form a right-handed triple helix. *Right:* A schematic model illustrates the triple-helical nature of the structure and shows the left-handed twist of the individual collagen α chains (red line). (b) View down the axis of the triple helix. The proton side chains of the glycine residues (orange) point into the very narrow space between the polypeptide chains in the center of the triple helix. In collagen mutations in which other amino acids replace glycine, the proton in glycine is replaced by larger groups that disrupt the packing of the chains and destabilize the triple-helical structure.

[Data from R. Z. Kramer et al., 2001, *J. Mol. Biol.* **311**:131, PDB ID 1bkv.]

There are several distinct cell-surface receptors for collagen IV and other types of collagen (other collagens are discussed in the next section). These cell-surface receptors include certain integrins, discoidin domain receptors 1 and 2 (which are tyrosine kinase receptors), glycoprotein VI (on platelets), leukocyte-associated Ig-like receptor-1, members of the mannose receptor family, and a modified form of the protein CD44. They can play critical roles in helping to assemble the ECM and in integrating cellular activity with the ECM.

The unique properties of each collagen isoform are due mainly to differences in (1) the number and lengths of the collagenous triple-helical segments; (2) the segments that flank or interrupt the triple-helical segments and that fold into other kinds of three-dimensional structures; and (3) covalent modification of the α chains (e.g., hydroxylation, glycosylation, oxidation, cross-linking). For example, the chains in type IV collagen are designated IVα chains. Mammals express six homologous IVα chains, which assemble into three different heterotrimeric type IV collagens with distinct properties. All subtypes of type IV collagen, however, form a 400-nm-long triple helix (Figure 20-27) that is interrupted about 24 times by nonhelical segments and flanked by a large globular domain at the C-terminus of the chain and a smaller globular domain at the N-terminus. The nonhelical regions introduce flexibility into the molecule. Through both lateral associations and interactions entailing the globular N- and C-termini, type IV collagen molecules assemble into a branching and covalently cross-linked, irregular two-dimensional

fibrous network that forms a lattice on which, together with the laminin lattice, the basal lamina is built (see Figures 20-24 and 20-27). Multiple, unusual sulfilimine (—S=N—) or thioether bonds between hydroxylysine (or lysine) and methionine residues covalently cross-link some adjacent C-terminal domains of type IV collagen molecules, and thus contribute to the stability of the network.

FIGURE 20-27 Structure and assembly of type IV collagen. (a) Schematic representation of type IV collagen. This 400-nm-long molecule has a small noncollagenous globular domain at the N-terminus and a large globular domain at the C-terminus. The collagenous triple helix is interrupted by nonhelical segments that introduce flexible kinks into the molecule. Lateral interactions between triple-helical segments, as well as head-to-head and tail-to-tail interactions between the globular domains, form dimers, tetramers, and higher order complexes, yielding a sheet-like network. See A. Boutaud et al., 2000, *J. Biol. Chem.* **275**:30716. (b) Electron micrograph of type IV collagen network formed in vitro. The lacy appearance results from the flexibility of the molecule, the side-to-side binding between triple-helical segments (white arrows), and the interactions between C-terminal globular domains (yellow arrows).

[Part (b) P. D. Yurchenco and G. C. Ruben, 1987, *J. Cell Biol.* **105**(6):2559–2568, Fig. 1c; https://doi.org/10.1083/jcb.105.6.2559.]

In the kidney, a double basal lamina called the *glomerular basement membrane* separates the epithelium that lines the urinary space from the endothelium that lines the surrounding blood-filled capillaries. Defects in this structure, which is responsible for

ultrafiltration of the blood and initial urine formation, can lead to renal failure. For instance, mutations that alter the C-terminal globular domain of certain IVα chains are associated with progressive renal failure as well as sensorineural hearing loss and ocular abnormalities, a condition known as *Alport's syndrome*. In *Goodpasture's syndrome*, a relatively rare autoimmune disease, antibodies bind to the α3 chains of type IV collagen found in the glomerular basement membrane and lungs. This binding sets off an immune response that causes cellular damage, resulting in progressive renal failure and pulmonary hemorrhage. ■

Perlecan, a Proteoglycan, Cross-Links Components of the Basal Lamina and Cell-Surface Receptors

Perlecan, the major secreted proteoglycan in basal laminae, consists of a large multidomain core protein (~470 kDa) to which polysaccharides are covalently attached. The core protein is made up of multiple repeats of five distinct domains, including laminin-like LG domains (3 copies), EGF-like domains (12 copies), and Ig domains (22 copies). The many globular repeats give it the appearance of an approximately 200-nm-long string of pearls when visualized by electron microscopy; hence the name *perlecan*. Perlecan contains three types of covalent polysaccharide chains: *N*-linked chains (see Chapter 14), *O*-linked chains, and

glycosaminoglycans (GAGs) (*O*-linked sugars and GAGs are discussed further in Section 20.4). GAGs are long, linear polymers of repeating disaccharides. Glycoproteins containing covalently attached GAG chains are called *proteoglycans*. Both the protein and the GAG components of perlecan contribute to its ability to incorporate into and define the structure and function of basal laminae. Because its multiple domains and its polysaccharide chains have distinct binding properties, perlecan binds to dozens of other molecules, including other ECM components (e.g., laminin, nidogen/entactin), cell-surface receptors, and polypeptide growth factors. Simultaneous binding to these molecules results in perlecan-mediated cross-linking. Perlecan can be found in basal laminae and in non–basal laminal ECM. The adhesion receptor dystroglycan can bind perlecan directly, via perlecan's LG domains, and indirectly, via its binding to laminin. In humans, mutations in the perlecan gene can lead either to dwarfism or to muscle abnormalities, apparently due to dysfunction of the neuromuscular junction that controls muscle firing.

KEY CONCEPTS OF SECTION 20.3

The Extracellular Matrix I: The Basal Lamina

- The matrisome is the ensemble of proteins that compose the ECM itself and associated proteins that covalently modify (e.g., chemically cross-link, phosphorylate, cleave) the ECM.
- The basal lamina, a thin meshwork of ECM molecules, separates most epithelia and other organized groups of cells from adjacent connective tissue. Together, the basal

lamina and the immediately adjacent collagen network form a structure called the *basement membrane*.

- Four ECM proteins are found in all basal laminae (see Figure 20-24): laminin (a multi-adhesive matrix protein), type IV collagen, perlecan (a proteoglycan), and nidogen/entactin.
- Adhesion receptors such as integrin anchor cells to the basal lamina, which in turn is connected to other ECM components (see Figure 20-1). Laminin in the basal lamina is the principal ligand of α6β4 integrin (see Table 20-4).
- Laminin and other multi-adhesive matrix proteins are multidomain molecules that bind multiple adhesion receptors and ECM components.
- The large, flexible molecules of type IV collagen interact end to end and laterally to form a mesh-like scaffold to which other ECM components and adhesion receptors can bind (see Figures 20-24 and 20-27).
- Type IV collagen is a member of the collagen family of proteins, which is distinguished by the presence of repeating tripeptide sequences of Gly-X-Y that give rise to the collagen triple-helical structure (see Figure 20-26). Different collagens are distinguished by the length and chemical modifications of their α chains and by the presence or absence of segments that interrupt or flank their triple-helical regions.
- Perlecan, a large, multidomain, secreted proteoglycan that is present primarily in basal laminae, binds many ECM components and adhesion receptors. Proteoglycans consist of membrane-associated or secreted core proteins covalently linked to one or more specialized polysaccharide chains called *glycosaminoglycans (GAGs)*.

20.4 The Extracellular Matrix II: Connective Tissue

Connective tissue, such as tendon and cartilage, differs from other solid tissues in that, rather than being filled primarily with cells, most of its volume is made up of extracellular matrix packed with insoluble protein fibers (see Figure 20-4). ECM in connective tissue has several key components, some of which are found in other types of tissues as well:

- *Collagens*, trimeric molecules that are often bundled together into fibers (fibrillar collagens)
- *Glycosaminoglycans (GAGs)*, specialized linear polysaccharide chains of specific repeating disaccharides that can be highly hydrated and confer diverse binding and physical properties (e.g., resistance to compression)
- *Proteoglycans*, glycoproteins containing one or more covalently bound GAG chains
- *Multi-adhesive proteins*, large multidomain proteins often comprising many copies ("repeats") of a few distinctive domains that bind to and cross-link a variety of adhesion receptors and ECM components
- *Elastin*, a protein that forms the amorphous core of elastic fibers

Collagen is the most abundant fibrous protein in connective tissue. Rubberlike elastin fibers, which can be stretched and relaxed, are

also present in deformable sites (e.g., skin, tendons, heart). The fibronectins, a family of multi-adhesive matrix proteins, form their own distinct fibrils in the ECM of most connective tissues. Although several types of cells are found in connective tissues, the various ECM components are produced largely by cells called **fibroblasts**. In this section, we explore the structure and function of the various ECM components in connective tissue, and we see how the ECM is degraded and remodeled by a variety of specialized proteases.

Fibrillar Collagens Are the Major Fibrous Proteins in the ECM of Connective Tissues

About 80–90 percent of the collagen in the body consists of **fibrillar collagens** (types I, II, and III), located primarily in connective tissues (see Table 20-5). Because of its abundance in tendon-rich tissue such as rat tail, type I collagen is easy to isolate and was the first collagen to be characterized. Its fundamental structural unit is a long (300 nm), thin (1.5 nm diameter) triple helix (see Figure 20-26) consisting of two α1(I) chains and one α2(I) chain, each 1050 amino acids in length. The triple-stranded molecules pack tightly together and wrap around one another, forming *microfibrils* that associate into higher order polymers called collagen *fibrils*, which in turn often aggregate into larger bundles called collagen *fibers* (Figure 20-28).

FIGURE 20-28 Biosynthesis of fibrillar collagens. Step 1: Procollagen α chains are synthesized on ribosomes associated with the endoplasmic reticulum (rough ER), and in the ER, asparagine-linked oligosaccharides are added to the C-terminal propeptide. Step 2: Propeptides associate to form trimers and are covalently linked by disulfide bonds, and selected residues in the Gly-X-Y triplet repeats are covalently modified [certain prolines and lysines are hydroxylated; galactose or galactose-glucose (hexagons) are attached to some hydroxylysines; prolines are cis → trans isomerized]. Step 3: The modifications facilitate zipper-like formation and stabilization of triple helices, and binding by the ER chaperone protein Hsp47, which may stabilize the helices or prevent premature aggregation of the trimers, or both. Steps 4 and 5: The folded procollagens are packaged into large transport vesicles with the help of specialized membrane proteins in the ER (not shown) and then transported to and through the Golgi complex, where some lateral association into small bundles takes place. The chains are then secreted (step 6), the N- and C-terminal propeptides are removed (step 7), and the trimers assemble into fibrils and are covalently cross-linked (step 8). The 67 nm staggering of the trimers gives the fibrils a striated appearance in electron micrographs (*inset*). Step 9: The fibrils can assemble into larger

and larger bundles, some of which form the tendons that attach muscle to bone. See A. V. Persikov and B. Brodsky, 2002, *Proc. Nat'l. Acad. Sci. USA* **99**:1101–1103.

[Electron micrograph republished with permission from John Wiley & Sons, Inc., from J. Gross, 1953, "Evaluation of Structural and Chemical Changes in Connective Tissue," *Ann. NY Acad. Sci*. **56**(4):674–683; permission conveyed through Copyright Clearance Center, Inc.]

Classes of collagen that are less abundant, but nevertheless important, include *fibril-associated collagens*, which link the fibrillar collagens to one another or to other ECM components; *sheet-forming* and *anchoring collagens*, which form two-dimensional networks in basal laminae (type IV) and connect the basal lamina in skin to the underlying connective tissue (type VII); *transmembrane collagens*, which function as adhesion receptors; and *host defense collagens*, which help the body recognize and eliminate pathogens. Interestingly, several collagens (e.g., types IX, XVIII, and XV) are also proteoglycans with covalently attached GAGs (see Table 20-5).

Fibrillar Collagen Is Secreted and Assembled into Fibrils Outside the Cell

Fibrillar collagens are secreted proteins, produced primarily by fibroblasts in the ECM. Collagen biosynthesis and secretion follow the normal pathway for a secreted protein, described in detail in Chapters 13 and 14. The collagen α chains are synthesized as longer precursors, called *pro-α chains*, by ribosomes attached to the endoplasmic reticulum (ER). The pro-α chains undergo a series of

covalent modifications and fold into triple-helical *procollagen* molecules before their transport from the ER to the Golgi complex and subsequent release from cells (see Figure 20-28). Specialized membrane proteins in the ER allow the packaging of the very large collagen molecules into large transport vesicles for transfer to the Golgi complex.

After the secretion of procollagen from the cell, extracellular peptidases remove the N-terminal and C-terminal propeptides. The resulting molecules, which consist almost entirely of a triple-stranded helix because of long stretches of the characteristic collagen repeating sequence motif Gly-X-Y, associate laterally to generate fibrils with a diameter of 50–200 nm. In fibrils, adjacent collagen molecules are displaced from one another by 67 nm, about one-quarter of their length. This staggered array produces a striated effect that can be seen in both light and electron microscopic images of collagen fibrils (see Figure 20-28, *inset*). The unique properties of the fibrillar collagens are mainly due to the formation of fibrils.

Short segments at either end of the fibrillar collagen α chains that are not composed of the repeating sequence motif Gly-X-Y, and thus are not triple-helical, are of particular importance in the formation of collagen fibrils. Lysine and hydroxylysine side chains in these segments are covalently modified by extracellular lysyl oxidases to form aldehydes in place of the amine group at the end of the side

chain. These reactive aldehyde groups form covalent cross-links with lysine, hydroxylysine, and histidine residues in adjacent molecules. The cross-links stabilize the side-by-side packing of collagen molecules and generate a very strong fibril. The removal of the terminal propeptides and covalent cross-linking take place in the extracellular space to prevent the potentially catastrophic assembly of large fibrils within the cell.

The post-translational modifications of pro-α chains are crucial for the formation of mature collagen molecules and their assembly into fibrils. Defects in these modifications have serious consequences, which ancient mariners frequently experienced. For example, ascorbic acid (vitamin C) is an essential cofactor for the hydroxylases responsible for adding hydroxyl groups to proline and lysine residues in pro-α chains. In cells deprived of ascorbate, as in the disease *scurvy*, the pro-α chains are not hydroxylated sufficiently to form stable triple-helical procollagen at normal body temperature, and the procollagen that forms cannot assemble into normal fibrils. Without the structural support of collagen, blood vessels, tendons, and skin become fragile. Fresh fruit in the diet can supply sufficient vitamin C to support the formation of normal collagen. Historically, British sailors were provided with limes to prevent scurvy, leading to their being called “limeys.” Mutations in lysyl hydroxylase genes can also cause connective-tissue defects. ■

Type I and II Collagens Associate with Nonfibrillar Collagens to Form Diverse Structures

Collagens differ in the structures of the fibers they form and in how these fibers are organized into networks. Of the predominant types of collagen found in connective tissues, type I collagen forms long fibers, whereas networks of type II collagen are more mesh-like. In tendons, for instance, the long type I collagen fibers connect muscles to bones and must withstand enormous forces. Because type I collagen fibers have great tensile strength, tendons usually can be stretched without being broken. Indeed, gram for gram, type I collagen is stronger than steel. Two quantitatively minor fibrillar collagens, type V and type XI, co-assemble into fibers with type I collagen, thereby regulating the structures and properties of the fibers. Incorporation of type V collagen, for example, results in smaller-diameter fibers.

Type I collagen fibrils are also used as the reinforcing rods in the construction of bone. Bones and teeth are hard and strong because they contain large amounts of dahllite, a crystalline calcium- and phosphate-containing mineral. Most bones are about 70 percent mineral and 30 percent protein, the vast majority of which is type I collagen. Bones form when certain cells (chondrocytes and osteoblasts) secrete collagen fibrils that are then mineralized by deposition of small dahllite crystals.

In many connective tissues, particularly skeletal muscle, proteoglycans and a fibril-associated collagen called *type VI collagen* are noncovalently bound to the sides of type I fibrils and may bind the fibrils together to form thicker collagen fibers (Figure 20-29a). Type VI collagen is unusual in that the molecule consists of a relatively short triple helix with globular domains at both ends. The lateral association of two type VI monomers generates an *antiparallel* dimer. The end-to-end association of these dimers through their globular domains forms type VI *microfibrils.* These microfibrils have a beads-on-a-string appearance, with about 60-nm-long triple-helical regions separated by 40-nm-long globular domains.

FIGURE 20-29 Interactions of fibrillar collagens with fibril-associated collagens. (a) In tendons, type I fibrils are all oriented in the direction of the stress applied to the tendon. Proteoglycans and type VI collagen bind noncovalently to type I fibrils, coating the surface. The microfibrils of type VI collagen, which contain globular and triple-helical segments, bind to type I fibrils and link them together into thicker fibers. See R. R. Bruns et al., 1986, *J. Cell Biol.* **103**:393. (b) In cartilage, type IX collagen molecules are covalently bound at regular intervals along type II fibrils. A chondroitin sulfate chain, covalently linked to the α2(IX) chain at the flexible kink, projects outward from the fibril, as does the globular N-terminal region. See L. M. Shaw and B. R. Olsen, 1991, *Trends Biochem. Sci.* **16**:191.

The fibrils of type II collagen, the major collagen in cartilage, are smaller in diameter than type I fibrils and are oriented randomly in a viscous proteoglycan matrix. The rigid collagen fibrils impart strength to the matrix and allow it to resist large deformations. Type II fibrils are cross-linked to matrix proteoglycans by type IX collagen, another fibril-associated collagen. Type IX collagen and several related types have two or three triple-helical segments connected by flexible kinks and a globular N-terminal segment (Figure 20-29b). The globular N-terminal segment of type IX collagen extends from the type II fibril at the end of one of its helical segments, as does a chondroitin sulfate GAG chain (chondroitin sulfate is described below) that is sometimes linked to one of the type IX chains. These protruding nonhelical structures are thought to anchor the type II fibril to proteoglycans and other components of the matrix. The interrupted triple-helical structure of type IX and related collagens prevents them from assembling into fibrils, although they can associate with fibrils formed from other collagen types and form covalent cross-links to them.

Mutations affecting type I collagen and its associated proteins cause a variety of human diseases. Certain mutations in the genes encoding the type I collagen α1(I) or α2(I) chains lead to *osteogenesis imperfecta*, or brittle-bone disease. Because every third position in a collagen α chain must be a glycine for the triple helix to form (see Figure 20-26), mutations of glycine to almost any other amino acid are deleterious, resulting in poorly formed and unstable helices. A

defect in only one of the three α chains in a collagen molecule can disrupt the whole molecule's triple-helical structure and function. A mutation in a single copy (allele) of either the α1(I) gene or the α2(I) gene, both located on autosomes, can cause this disorder. Thus it normally shows autosomal dominant inheritance (see Chapter 6).

Absence or malfunctioning of fibril-associated collagen in muscle tissue due to mutations in the type VI collagen genes cause dominant or recessive congenital muscular dystrophies with generalized muscle weakness, respiratory insufficiency, muscle wasting, and muscle-related joint abnormalities. Skin abnormalities have also been reported with type VI collagen disease. ■

Proteoglycans and Their Constituent GAGs Play Diverse Roles in the ECM

As we saw with perlecan in the basal lamina, proteoglycans play an important role in cell-matrix adhesion. Proteoglycans are a subset of secreted or cell-surface glycoproteins containing covalently linked, specialized polysaccharide chains called **glycosaminoglycans (GAGs)**. GAGs are long linear polymers of specific repeating disaccharides. Usually one sugar is either a uronic acid (D-glucuronic acid or L-iduronic acid) or D-galactose; the other sugar is *N*-acetylglucosamine or *N*-acetylgalactosamine (Figure 20-30). One or both of the sugars contain at least one anionic group (carboxylate

or sulfate). Thus each GAG chain bears many negative charges. GAGs are classified into several major types based on the nature of the repeating disaccharide unit: heparan sulfate, chondroitin sulfate, dermatan sulfate, keratan sulfate, and hyaluronan (see Figure 20-30). A hypersulfated form of heparan sulfate called *heparin*, produced mostly by mast cells, plays a key role in allergic reactions. It is also used medically as an anticlotting drug because of its ability to activate a natural clotting inhibitor called *antithrombin III*.

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

FIGURE 20-30 The repeating disaccharides of glycosaminoglycans (GAGs). Each of the four classes of GAGs is formed by polymerization of monomeric units into repeats of a particular disaccharide and subsequent modifications, including addition of sulfate groups and inversion (epimerization) of the carboxyl group on carbon 5 of D-glucuronic acid to yield L-iduronic acid. The squiggly lines represent covalent bonds that are oriented either above (D-glucuronic acid) or below (L-iduronic acid) the ring. Heparin is generated by hypersulfation of heparan sulfate, whereas hyaluronan is not sulfated.

With the exception of hyaluronan, which is discussed below, all the major GAGs occur naturally as components of proteoglycans. Like other secreted and transmembrane glycoproteins, proteoglycan core proteins are synthesized in the endoplasmic reticulum, and the GAG chains are assembled on and covalently attached to these cores in the Golgi complex. To generate heparan or chondroitin sulfate chains, a three-sugar linker is first attached to the hydroxyl side chains of certain serine residues in a core protein (Figure 20-31a);

thus these GAGs are ***O*-linked oligosaccharides**, several examples of which are shown in Figure 20-31.

FIGURE 20-31 Hydroxyl *O*-linked oligosaccharides. (a) Synthesis of a GAG, in this case chondroitin sulfate, is initiated by transfer of a xylose (Xyl) residue to a serine residue in the core protein, most likely in the Golgi complex, followed by sequential addition of two galactose (Gal) residues. Glucuronic acid (GlcUA)

and *N*-acetylgalactosamine (GalNAc) residues are then added sequentially to these linking sugars and some of the GalNAc monomers are sulfated, forming the chondroitin sulfate chain. Heparan sulfate chains are connected to core proteins by the same three-sugar linker. Keratan sulfate GAGs are covalently attached to proteins via *N*-linked rather than *O*-linked connections. (b) Mucin-like *O*-linked chains are covalently bound to glycoproteins via an *N*-acetylgalactosamine (GalNAc). (c) In the integral membrane protein α-dystroglycan on cell surfaces, a complex polysaccharide is attached to hydroxyl side chains via an O-mannose (O-Man). A polymer of the GlcUA-Xyl disaccharide ($[-\mathrm{Xyl\text{-}GlcUA}]_n$) called *matriglycan* is attached to a phosphorylated *O*-linked mannose via an oligosaccharide containing *N*-acetylglucosamine (GlcNAc), ribitol 5-phosphate (Ribito5P), Xyl, and GlcUA. Matriglycan provides a binding site for ECM molecules, such as laminin and perlecan (described in detail in Section 20.5).

O-linked oligosaccharides are attached to the hydroxyl side chains of specific serine and theonine residues in a variety of secreted proteins and the exoplasmic (extracellular) domains of some membrane proteins. For example, mucin-like *O*-linked chains are covalently bound to glycoproteins via an *N*-acetylgalactosamine (GalNAc) monosaccharide to which are covalently attached a variety of other sugars, often including sialic acid (SA; Figure 20-31b). The high concentration of long *O*-linked chains on mucin glycoproteins on the apical plasma membranes of epithelial cells apparently contributes to the bending of the membranes and the formation of microvilli (see Figures 20-11, 17-1, and 17-2). The only *O*-linked glycoproteins in baker's yeast are mannose-linked (O-Man). In other eukaryotes (not in nematode worms or plants), certain specialized *O*-linked sugars are bound to proteins via mannose

monosaccharides. Some proteins, including classical cadherins and protocadherins (Section 20.2), have relatively short O-mannose linked oligosaccharides. Others have longer oligosaccharides attached via the O-mannose, such as that attached to the cell-surface protein dystroglycan (Figure 20-31c; described in detail in Section 20.5).

In contrast to protein-linked heparan or chondroitin sulfate chains, the linkers for the addition of keratan sulfate chains are oligosaccharide chains attached to asparagine residues; such ***N*-linked oligosaccharides** are present in many glycoproteins (see Chapters 13 and 14), although only a subset carry GAG chains. All GAG chains are elongated by the alternating addition of sugar monomers to form the disaccharide repeats characteristic of a particular GAG; the chains are often modified subsequently by the covalent linkage of small molecules such as sulfate. The mechanisms responsible for determining which proteins are modified with GAGs, the sequence of disaccharides to be added, the sites to be sulfated, and the lengths of the GAG chains are unknown. The ratio of polysaccharide to protein in all proteoglycans is much higher than that in most other glycoproteins.

Function of GAG Chain Modifications

Similar to the sequence of amino acids in proteins, the arrangement of the sugar residues in GAG chains and the modification of specific

sugars in those chains can determine their function and that of the proteoglycans that contain them. For example, groupings of certain modified sugars in the GAG chains of heparin sulfate proteoglycans can control the binding of growth factors to certain receptors or the activities of proteins in the blood-clotting cascade.

In the past, the chemical and structural complexity of proteoglycans posed a daunting barrier to analyzing and understanding their structures and their many diverse functions. In recent years, investigators employing classic and state-of-the-art biochemical techniques, mass spectrometry, and genetics have begun to elucidate the detailed structures and functions of these ubiquitous ECM molecules. The results of ongoing studies suggest that sets of sugar-residue sequences containing common modifications, rather than single unique sequences, are responsible for specifying distinct GAG functions. A case in point is a set of five-residue (pentasaccharide) sequences found in a subset of heparin GAGs that controls the activity of antithrombin III (ATIII), an inhibitor of the key blood-clotting protease thrombin. When these pentasaccharide sequences in heparin are sulfated at two specific positions (Figure 20-32), heparin can activate ATIII, thereby inhibiting clot formation. Several other sulfates can be present in the active pentasaccharide in various combinations, but they are not essential for the anticlotting activity of heparin. The rationale for generating sets of similar active sequences rather than a single, unique sequence is not well understood.

FIGURE 20-32 The pentasaccharide GAG sequence that regulates the activity of antithrombin III (ATIII). Sets of modified five-residue sequences in the much longer GAG called *heparin* with the composition shown here bind to ATIII and activate it, thereby inhibiting blood clotting. The sulfate groups in red type are essential for this heparin function; the modifications in blue type may be present but are not essential. Other sets of modified GAG sequences are thought to regulate the activity of other target proteins.

Diversity of Proteoglycans

The proteoglycans constitute a remarkably diverse group of molecules that are abundant in the ECM of all animal tissues and are also expressed on the cell surface. For example, of the five major classes of heparan sulfate proteoglycans, three are located in the ECM (perlecan, agrin, and type XVIII collagen) and two are cell-surface proteins. The latter include integral membrane proteins (syndecans) and GPI-anchored proteins (glypicans); the GAG chains in both types of cell-surface proteoglycans extend into the extracellular space. The sequences and lengths of proteoglycan core proteins vary considerably, and the number of attached GAG chains ranges from just a few to more than 100. Moreover, a core protein is

often linked to two different types of GAG chains, generating a hybrid proteoglycan. The basal laminal proteoglycan perlecan is primarily a heparan sulfate proteoglycan with three to four GAG chains, although it can sometimes have a bound chondroitin sulfate chain. Additional diversity in proteoglycans occurs because the numbers, compositions, and sequences of the GAG chains attached to otherwise identical core proteins can differ considerably. Laboratory generation and analysis of mutants with defects in proteoglycan production in *Drosophila*, *C. elegans*, and mice have clearly shown that proteoglycans play critical roles in development; for example, as participants in various signaling pathways (see Chapter 16 for examples in the TGF-β and Wnt pathways).

Syndecans are cell-surface proteoglycans expressed by epithelial and nonepithelial cells that bind to collagens and multi-adhesive matrix proteins such as fibronectin, anchoring cells to the ECM. Like that of many integral membrane proteins, the cytosolic domain of syndecan interacts with the actin cytoskeleton and in some cases with intracellular regulatory molecules. In addition, cell-surface proteoglycans such as syndecan bind many protein growth factors and other external signaling molecules, thereby helping to regulate cellular metabolism and function. For instance, syndecans in the hypothalamic region of the brain modulate feeding behavior in response to food deprivation. They do so by participating in the binding to cell-surface receptors of antisatiety peptides that help control feeding behavior. In the fed state, the syndecan extracellular

domain decorated with heparan sulfate GAG chains is released from the cell surface by proteolysis, thus suppressing the activity of the antisatiety peptides and feeding behavior. In mice engineered to overexpress the *syndecan-1* gene in the hypothalamic region of the brain and other tissues, normal control of feeding by antisatiety peptides is disrupted, and the animals overeat and become obese.

Hyaluronan Resists Compression, Facilitates Cell Migration, and Gives Cartilage Its Gel-Like Properties

Hyaluronan, also called *hyaluronic acid (HA)* or *hyaluronate*, is a nonsulfated GAG (see Figure 20-30a) made by a plasma-membrane-bound enzyme called *HA synthase* and is secreted directly into the extracellular space as it is synthesized. (A similar approach is used by plant cells to make the ECM component cellulose.) Hyaluronan is a major component of the ECM that surrounds migrating and proliferating cells, particularly in embryonic tissues. In addition, it forms the backbone of complex proteoglycan aggregates found in many ECMs, particularly cartilage. Because of its remarkable physical properties, hyaluronan imparts stiffness and resilience as well as a lubricating quality to many types of connective tissue such as joints.

Hyaluronan molecules range in length from a few disaccharide repeats to about 25,000. The typical hyaluronan in joints such as the elbow has 10,000 repeats for a total mass of 4×10^6 Da and a length of 10 μm (about the diameter of a small cell). Individual segments of a hyaluronan molecule fold into a rodlike conformation because of the β glycosidic linkages between the sugars and extensive intrachain hydrogen bonding. Mutual repulsion between negatively charged carboxylate groups that protrude outward at regular intervals also contributes to these locally rigid structures. Overall, however, hyaluronan is not a long, rigid rod like fibrillar collagen; rather, it is very flexible in solution, bending and twisting into many conformations, forming a random coil.

Because of the large number of anionic residues on its surface, the typical hyaluronan molecule binds a large amount of water and behaves as if it were a large hydrated sphere with a diameter of about 500 nm. As the concentration of hyaluronan increases, the long chains begin to entangle, forming a viscous gel. Even at low concentrations, hyaluronan forms a hydrated gel; when placed in a confining space, such as that between two cells, the long hyaluronan molecules tend to push outward. This outward pushing creates a swelling, or *turgor pressure*, within the extracellular space. In addition, the binding of cations by carboxylate (COO^-) groups on the surface of hyaluronan increases the concentration of ions and thus the osmotic pressure in the gel. As a result, large amounts of water are taken up, contributing to the turgor pressure. These

swelling forces give connective tissues their ability to resist compression forces, in contrast to collagen fibers, which are best able to resist stretching forces. Other highly charged GAG chains are similarly hydrated.

Hyaluronan is bound to the surface of many migrating cells by a number of adhesion receptors, such as the receptor called *CD44*, which contains hyaluronan-binding domains, each with a similar three-dimensional conformation. Because of its loose, hydrated, porous nature, the hyaluronan coating bound to cells appears to keep them apart from one another, giving them the freedom to move about and proliferate. The cessation of cell movement and the initiation of cell-cell attachments are frequently correlated with a decrease in hyaluronan, a decrease in hyaluronan receptors, and an increase in the extracellular enzyme hyaluronidase, which degrades hyaluronan in the matrix. These alterations of hyaluronan are particularly important during the many cell migrations that facilitate differentiation and in the release of a mammalian egg cell from its surrounding cells after ovulation.

The predominant proteoglycan in cartilage, called *aggrecan*, assembles with hyaluronan into very large aggregates, illustrative of the complex structures that proteoglycans sometimes form. The backbone of this proteoglycan aggregate is a long molecule of hyaluronan to which multiple aggrecan molecules are bound tightly but noncovalently (Figure 20-33). A single hyaluronan-aggrecan

aggregate, one of the largest macromolecular complexes known, can be more than 4 μm long and have a volume larger than that of a bacterial cell. These aggregates give cartilage its unique gel-like properties and its resistance to deformation, essential for distributing the load in weight-bearing joints.

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

FIGURE 20-33 Structure of proteoglycan aggregate from cartilage. (a) Electron micrograph of an aggrecan aggregate from fetal bovine epiphyseal cartilage (artificially colored). Aggrecan core proteins are bound at ~40-nm intervals to a molecule of hyaluronan. (b) Schematic representation of an aggrecan monomer bound to hyaluronan. In aggrecan, both keratan sulfate and chondroitin sulfate chains are attached to the core protein. The N-terminal domain of the core protein binds noncovalently to a hyaluronan molecule. Binding is facilitated by a link protein, which binds to both the hyaluronan molecule and the aggrecan core protein. Each aggrecan core protein has 127 Ser-Gly sequences at which GAG chains can be added. The molecular weight of an aggrecan monomer averages 2×10^6. The entire aggregate, which may contain upward of 100 aggrecan monomers, has a molecular weight in excess of 2×10^8 and is about as large as the bacterium *Escherichia coli*.

[Part (a) republished with permission from Elsevier, from J. A. Buckwalter and L. Rosenberg, 1983, "Structural Changes During Development in Bovine Fetal Epiphyseal Cartilage," *Collagen Rel. Res.* **3**(6):489–504; permission conveyed through Copyright Clearance Center, Inc.]

The aggrecan core protein (~250,000 MW) has one N-terminal globular domain that binds with high affinity to a specific decasaccharide sequence within hyaluronan. This specific sequence is generated by covalent modification of some of the repeating disaccharides in the hyaluronan chain. The interaction between aggrecan and hyaluronan is facilitated by a link protein that binds to both the aggrecan core protein and hyaluronan (Figure 20-33b). Aggrecan and the link protein have in common a *link* domain, about 100 amino acids long, that is found in numerous ECM and cell-surface hyaluronan-binding proteins in both cartilaginous and noncartilaginous tissues. These proteins almost certainly arose in

the course of evolution from a single ancestral gene that encoded just this domain.

Fibronectins Connect Cells and ECM, Influencing Cell Shape, Differentiation, and Movement

Many different cell types synthesize **fibronectin**, an abundant multi-adhesive matrix protein found in all vertebrates. The discovery that fibronectin functions as an adhesion molecule stemmed from observations that it is present on the surfaces of normal fibroblasts, which adhere tightly to petri dishes in laboratory experiments, but is absent from the surfaces of tumorigenic (i.e., cancerous) cells, which adhere weakly. The 20 or so isoforms of fibronectin are generated by alternative splicing of the RNA transcript produced from a single gene (see Figure 5-28). Fibronectins are essential for the migration and differentiation of many cell types in embryogenesis. These proteins are also important for wound healing because they promote blood clotting and facilitate the migration of macrophages and other immune-system cells into the affected area.

Fibronectins help attach cells to the ECM by binding to other ECM components, particularly fibrillar collagens and heparan sulfate proteoglycans, and to adhesion receptors such as integrins (see

Figure 20-2). Through their interactions with adhesion receptors, fibronectins influence the shape and movement of cells and the organization of the cytoskeleton. Conversely, by regulating their receptor-mediated attachments to fibronectin and other ECM components, cells can sculpt the immediate ECM environment to suit their needs.

Fibronectins are dimers of two similar polypeptides linked at their C-termini by two disulfide bonds; each chain is about 60–70 nm long and 2–3 nm thick. Partial digestion of fibronectin with small amounts of proteases and analysis of the fragments showed that each chain comprises several functional regions with different ligand-binding specificities (Figure 20-34a). Each region, in turn, contains multiple copies of certain domain-encoding sequences that can be classified into one of three types. These domains are designated fibronectin type I, II, and III repeats, on the basis of similarities in amino acid sequence, although the sequences of any two repeats of a given type are not identical. These linked repeats give the molecule the appearance of beads on a string. The combination of the different repeats composing the regions confers on fibronectin its ability to bind multiple ligands.

FIGURE 20-34 Organization of fibronectin and its binding to integrin. (a) Scale model of fibronectin is shown docked by two type III repeats to the extracellular domains of integrin. Only one of the two similar chains, which are linked by disulfide bonds near their C-termini, in the dimeric fibronectin molecule is shown. Each chain contains about 2446 amino acids and is composed of three types of repeating amino acid sequences (type I, II, or III repeats) or domains. The EIIIA, EIIIB — both type III repeats — and IIICS domain are variably spliced into the structure at locations indicated by arrows. Circulating fibronectin lacks EIIIA, EIIIB, or both. At least five different sequences may be present in the IIICS region as a result of alternative splicing (see Figure 5-28). Each chain contains several multi-repeat-containing regions, some of which contain specific binding sites for heparan sulfate, fibrin (a major constituent of blood clots), collagen, and cell-surface integrins. The integrin-binding domain is also known as the *cell-binding domain*. Structures of fibronectin's domains were determined from fragments of the molecule. (b) A high-resolution structure shows that the RGD sequence motif extends outward in a loop from its compact type III domain on the same side of fibronectin as the synergy region, which also contributes to high-affinity binding to integrins.

[Data from D. J. Leahy, I. Aukhil, and H. P. Erickson, 1996, *Cell* **84**:155, PDB ID 1fnf.]

One of the type III repeats in the cell-binding region of fibronectin mediates binding to certain integrins. The results of studies with synthetic peptides corresponding to parts of this repeat identified the tripeptide sequence Arg-Gly-Asp, called the *RGD motif*, as the minimal sequence within this repeat required for recognition by those integrins. In one study, heptapeptides with and without the

RGD motif were tested for their ability to mediate the adhesion of rat kidney cells to a culture dish. The results showed that heptapeptides containing the RGD motif mimicked intact fibronectin's ability to stimulate integrin-mediated adhesion, whereas variant heptapeptides lacking this sequence were ineffective (Figure 20-35).

EXPERIMENTAL FIGURE 20-35 A specific tripeptide sequence (RGD) in the cell-binding region of fibronectin is required for cell adhesion. The cell-binding region of fibronectin contains an integrin-binding hexapeptide sequence, GRGDSP in the single-letter amino acid code. Together with an additional C-terminal cysteine (C)

residue, this heptapeptide and several variants were synthesized chemically. Different concentrations of each synthetic peptide were added to polystyrene dishes that had the protein immunoglobulin G (IgG) firmly attached to their surfaces; the peptides were then chemically cross-linked to the IgG. Subsequently, cultured normal rat kidney cells were added to the dishes and incubated for 30 minutes to allow adhesion. After the unbound cells were washed away, the relative amounts of cells that had adhered firmly were determined by staining the bound cells with a dye and measuring the intensity of the staining with a spectrophotometer. The results shown here indicate that cell adhesion increased above the background level with increasing peptide concentration for those peptides containing the RGD motif, but not for the variants lacking this sequence (modification underlined).

[Data from M. D. Pierschbacher and E. Ruoslahti, 1984, *Proc. Nat'l. Acad. Sci. USA* **81**:5985.]

A three-dimensional model of fibronectin binding to integrin, based on partial structures of both fibronectin and integrin, has been assembled. In a high-resolution structure of the integrin-binding fibronectin type III repeat and its neighboring type III domain, the RGD motif is at the apex of a loop that protrudes outward from the molecule, in a position facilitating binding to integrins (Figure 20-34b). Although the RGD motif is required for binding to several different integrins, its affinity for integrins is substantially less than that of intact fibronectin or of the entire cell-binding region in fibronectin. Thus structural features near the RGD motif in fibronectins (e.g., parts of adjacent repeats, such as the synergy region; see Figure 20-34b) and in other RGD-containing proteins must enhance their binding to certain integrins. Moreover, the simple, soluble dimeric forms of fibronectin produced by the liver or by fibroblasts are initially in a nonfunctional conformation that

binds poorly to integrins because the RGD motif is not readily accessible. The adsorption of fibronectin onto a collagen matrix or basal lamina — or, experimentally, to a plastic tissue culture dish — results in a conformational change that enhances the ability of fibronectin to bind to cells. Possibly, this conformational change increases the accessibility of the RGD motif for integrin binding.

Microscopy and other experimental approaches (e.g., biochemical-binding experiments) have demonstrated the role of integrins in cross-linking fibronectin and other ECM components to the cytoskeleton. For example, the colocalization of cytoskeletal actin filaments and integrins within cells can be visualized by fluorescence microscopy (Figure 20-36a). The binding of cell-surface integrins to fibronectin in the ECM induces the actin cytoskeleton–dependent movement of some integrin molecules in the plane of the plasma membrane. The ensuing mechanical tension due to the relative movement of different integrins bound to a single fibronectin dimer stretches the fibronectin (see Figure 20-9), a mechanosensor, and promotes self-association of fibronectins into multimeric fibrils.

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

EXPERIMENTAL FIGURE 20-36 Integrins mediate linkage between fibronectin in the ECM and the cytoskeleton. (a) Immunofluorescent micrograph of a fixed cultured fibroblast showing colocalization of the α5β1 integrin (green) and actin-containing stress fibers (red). The cell was incubated with two types of monoclonal antibodies: an integrin-specific antibody linked to a green-fluorescing dye and an actin-specific antibody linked to a red-fluorescing dye. Stress fibers are long bundles of actin microfilaments that radiate inward from

points where the cell contacts a substratum. At the distal ends of these fibers, near the plasma membrane, the coincidence of actin and fibronectin-binding integrin produces a yellow fluorescence. (b) Electron micrograph of the junction of fibronectin and actin fibers in a cultured fibroblast. Individual actin-containing 7 nm microfilaments, components of a stress fiber, end at the obliquely sectioned cell membrane. The microfilaments appear aligned with and in close proximity to the thicker, densely stained fibronectin fibrils on the outside of the cell.

[Part (a) J. L. Duband et al., 1988, *J. Cell Biol.* **107**:1385–1396, cover; https://doi.org/10.1083/jcb.107.4.1385. Part (b) republished with permission from Elsevier, from I. I. Singer, 1979, "The Fibronexus: A Transmembrane Association of Fibronectin-Containing Fibers and Bundles of 5 nm Microfilaments in Hamster and Human Fibroblasts," *Cell* **16**(3):675–685; permission conveyed through Copyright Clearance Center, Inc.]

The force needed to unfold and expose functional self-association sites in fibronectin is much less than that needed to disrupt fibronectin-integrin binding. Thus fibronectin molecules remain bound to integrin while cell-generated mechanical forces induce fibril formation. In effect, the integrins, through adapter proteins, transmit the intracellular forces generated by the actin cytoskeleton to extracellular fibronectin (inside-out signaling via mechanotransduction). Gradually, the initially formed fibronectin fibrils mature into highly stable matrix components by covalent cross-linking. In some electron micrographs, exterior fibronectin fibrils appear to be aligned in a seemingly continuous line with bundles of actin fibers within the cell (Figure 20-36b). These observations and the results from other studies provided the first example of a molecularly well-defined adhesion receptor forming a

bridge between the intracellular cytoskeleton and the ECM components — a phenomenon now known to be widespread.

Elastic Fibers Permit Many Tissues to Undergo Repeated Stretching and Recoiling

Elastic fibers are found in the ECM of a wide variety of tissues that are subject to mechanical strain or deformation, such as the lungs, which expand and contract during breathing (Figure 20-37a); the blood vessels, through which blood pulses due to the heartbeat; and the skin and many other tissues that stretch and contract. Elastic fibers permit the rubberlike reversible elastic stretching and recoiling of these tissues.

FIGURE 20-37 Elastic and collagen fibers in connective tissue. (a) Light-microscopic image of loose connective tissue from the lung. Collagen fibers (bundles of collagen fibrils) are stained pink; elastic fibers and nuclei of cells are stained purple. (b) Longitudinal and (c) cross-sectional electron microscopic images of elastic fibers and collagen fibrils (coll) in the skin of a mouse. The elastic fibers have a solid core of elastin (e) integrated into and surrounded by a bundle of microfibrils (mf). Scale bars, 0.25 μm.

[Parts (b) and (c) republished with permission from Elsevier, from J. Choi et al., 2009, "Analysis of Dermal Elastic Fibers in the Absence of Fibulin-5 Reveals Potential Roles for Fibulin-5 in Elastic Fiber Assembly," *Matrix Biol*. **28**(4):211–220; permission conveyed through Copyright Clearance Center, Inc.]

The major component of an elastic fiber, which can be several hundred to several thousand nanometers in diameter, is an insoluble, amorphous core composed of the protein **elastin**. Elastin

consists of aggregates of monomeric *tropoelastin* molecules that are covalently cross-linked via a lysyl oxidase–mediated process similar to that seen in collagen. Repetitive proline- and glycine-enriched hydrophobic sequence motifs contribute to the ability of tropoelastins to self-associate, extend under stress, and recoil efficiently after stretching. The elastin core is surrounded by a collection of 10–12-nm-diameter microfibrils (Figure 20-37b) made up of the proteins fibrillin, fibulin, and associated proteins such as LTBPs (*l*atent *T*GF-β *b*inding *p*roteins). The microfibrils serve as scaffolds for the assembly of the elastic fiber's core. Elastin-free microfibrils are found in the eye, where they transmit muscular force to reshape the lens for focusing and may provide structural support to the cornea.

Similar to other components of the ECM, microfibrils participate in cell signaling. In the secretory pathway, LTBPs bind the inactive form of the secreted signaling protein transforming growth factor β (TGF-β; a cytokine, see Figure 16-22) prior to their co-secretion and incorporation into microfibrils. Biomechanical stress mediated by cell-surface integrins binding to and pulling on the LTBP/TGF-β complex or proteolytic cleavage are thought to be the direct cause of active TGF-β release from the ECM and subsequent signaling (see Figure 16-22). Similar integrin-mediated activation of the LTBP/TGF-β complex bound to other ECM proteins provides active TGF-β for regulation of a wide variety of biological processes.

A variety of diseases, many involving skeletal and cardiovascular abnormalities, are consequences of mutations in the genes encoding the structural proteins of elastic fibers or the proteins that contribute to their proper assembly. For example, mutations in the *fibrillin-1* gene cause Marfan syndrome, whose varied symptoms can include bone overgrowth, loose joints, abnormally long extremities and face, and cardiovascular defects due to weakness in the walls of the aorta and other blood vessels. There has been considerable speculation that President Abraham Lincoln's unusually tall, elongated body may have been a consequence of Marfan syndrome. ■

In mammals, most tropoelastin synthesis occurs immediately before and after birth during the late fetal and neonatal periods. Thus most of the body's elastin needs to be very durable, lasting an entire lifetime. The extraordinary stability of elastin has been measured in a variety of ways. Pulse-chase experiments (see Chapter 3) using radioactive amino acid administration can be used to measure the life span of elastin in animals. In humans, two other methods employed to study the longevity of elastin have revealed that the mean lifetime of an elastin molecule in human lungs is about 70 years! The first method takes advantage of a naturally occurring phenomenon: the slow, natural rate of conversion of L-aspartic acid — incorporated into proteins during their synthesis — to D-aspartic acid. Thus the age of a long-lived protein can be estimated using chemical analysis to determine what fraction of its L-aspartic acid

has been converted over time to the D isomer, together with knowledge of the age of the tissue from which it was isolated. The second method is a variation on the classic pulse-chase experiments used in the laboratory. As a consequence of nuclear weapons testing in the 1950s and 1960s, ^{14}C was introduced into the atmosphere and hence the food chain. This environmental ^{14}C has been used as the radioactive *pulse* in what is essentially a pulse-chase experiment to determine the stability of proteins of interest.

Metalloproteases Remodel and Degrade the Extracellular Matrix

Many key physiological processes, including morphogenesis during development, control of cellular proliferation and motility, response to injury, and even survival, require not only the production of ECM, but also its remodeling or degradation. Because of its enormous importance as a key element in the extracellular environment of multicellular organisms, remodeling and degradation of the ECM must be carefully controlled. Degradation of the ECM is often mediated by zinc-dependent ECM metalloproteases. Given the wide array of ECM components, it is not surprising that there are many such metalloproteases with varying substrate specificities and sites of expression. In many cases, their names incorporate the names of their substrates, as for the metalloproteases called *collagenases*, *gelatinases*, *elastases*, and *aggrecanases*. Some are secreted into the

extracellular fluid, and others are closely associated with the plasma membranes of cells, either tightly bound in a noncovalent association with the membrane or as integral membrane proteins. Many are initially synthesized as inactive precursors that must be specifically activated to function.

ECM metalloproteases are divided into three major subgroups based on the enzymes' structures: **matrix metalloproteases (MMPs)** (of which there are 23 in humans), *a d*isintegrin *a*nd *m*etalloproteinases (ADAMs), and *ADAM*s with *t*hrombo*s*pondin motifs (ADAMTSs). These proteases can degrade ECM components as well as non-ECM components such as adhesion receptors. Indeed, a key function of ADAMs is cleaving extracellular domains from integral membrane proteins. In Chapter 16 we learned how ADAMs play key roles in signaling by Notch and EGF receptors. One mechanism used to control the activities of these proteases is the production of protein inhibitors called *TIMPs* (*t*issue *i*nhibitors of *m*etallo*p*roteinases) and *RECK* (*re*version-inducing–*c*ysteine-rich protein with *k*azal motifs). Some of these inhibitors have their own cell-surface receptors and functions independent of their ability to inhibit metalloproteinases. ECM-degrading proteases are associated with a variety of diseases, the best known of which is metastatic (spreading) cancer (see Chapter 25).

KEY CONCEPTS OF SECTION 20.4

The Extracellular Matrix II: Connective Tissue

- Connective tissue, such as tendon and cartilage, differs from other solid tissues in that most of its volume is made up of extracellular matrix (ECM) rather than cells (see Figure 20-4).
- The synthesis of fibrillar collagen (e.g., types I, II, and III) begins inside the cell with the chemical modification of newly made α chains and their assembly into triple-helical procollagen within the endoplasmic reticulum. After secretion, procollagen molecules are cleaved, associate laterally, and are covalently cross-linked into bundles called *fibrils*, which can form larger assemblies called *fibers* (see Figure 20-28).
- The various collagens are distinguished by the ability of their helical and nonhelical regions to associate into fibrils, to form sheets, or to cross-link other collagen types (see Table 20-5).
- Proteoglycans consist of membrane-associated or secreted core proteins covalently linked to one or more glycosaminoglycan (GAG) chains, which are linear polymers of disaccharides that are often modified by sulfation.
- Cell-surface proteoglycans such as the syndecans facilitate cell-matrix interactions and help present certain external signaling molecules to their cell-surface receptors.
- Hyaluronan, a highly hydrated GAG, is a major component of the ECM of migrating and proliferating cells. Certain adhesion receptors bind hyaluronan to cells.
- Large proteoglycan aggregates containing a central hyaluronan molecule noncovalently bound to the core proteins of proteoglycan molecules (e.g., aggrecan) contribute to the ability of the matrix to resist compression forces (see Figure 20-33).
- Fibronectins are abundant multi-adhesive matrix proteins that play a key role in migration and cellular differentiation. They contain binding sites for integrins and ECM components (collagens, proteoglycans) and thus can attach cells to the ECM (see Figure 20-34).
- The tripeptide RGD motif Arg-Gly-Asp, found in fibronectins and some other matrix proteins, is recognized by several integrins.
- Elastic fibers permit repeated stretching and recoiling of tissues because of their highly elastic core of cross-linked, amorphous elastin, which is surrounded by a network of microfibrils that help assemble the fibers and regulate signaling mediated by TGF-β.
- The remodeling or degradation of ECM is mediated by a large number of secreted and cell-membrane-associated zinc metalloproteases that fall into several families (MMPs, ADAMs, ADAMTSs) and whose activities are regulated by protein inhibitors (TIMPs and RECK).

20.5 Adhesive Interactions in Motile and Nonmotile Cells

After adhesive interactions in epithelia form during differentiation, they are often very stable and can last throughout the life span of the cells or until the epithelium undergoes further differentiation. Although such long-lasting nonmotile adhesion also exists in nonepithelial tissues, some nonepithelial cells must be able to crawl across or through a layer of ECM or other cells. Moreover, during development or wound healing and in certain pathological states (e.g., cancer), epithelial cells can transform into more motile cells (the epithelial-to-mesenchymal transition). Changes in expression of adhesion molecules play a key role in this transformation, as they do in other biological processes involving cell movement, such as the crawling of white blood cells into tissue sites of infection. In this section, we describe various cell-surface structures that mediate transient adhesive interactions that are especially adapted for the movement of cells as well as those that mediate long-lasting adhesion. The intracellular mechanisms used to generate the mechanical forces that propel cells and modify their shapes are covered in Chapters 17 and 18.

Integrins Mediate Adhesion and Relay Signals Between Cells and Their Three-

Dimensional Environment

As already discussed, integrins can connect epithelial cells to the basal lamina and, through adapter proteins, to intermediate filaments of the cytoskeleton (see Figure 20-1). In both nonepithelial and epithelial cells, integrins form a bridge between the ECM and the cytoskeleton. In epithelial and nonepithelial cells, integrins in the plasma membrane are also clustered with other molecules in various focal contacts (focal adhesions) and focal contact–like adhesive structures called *focal complexes*, *3-D adhesions*, and *fibrillar adhesions*, as well as in circular adhesions called *podosomes*. These structures are multiprotein complexes that mediate (1) cell adhesion to the ECM — for example, via integrin binding to fibronectin (see Figure 20-36), collagen or laminin, (2) integrin association with the actin cytoskeleton, (3) adhesion-dependent outside-in and inside-out signaling (see Figure 20-8), and (4) mechanosensory coupling between cells and their environments. These complexes are readily observed by fluorescence microscopy with the use of antibodies that recognize integrins or other molecules clustered with them (Figure 20-38).

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

EXPERIMENTAL FIGURE 20-38 Integrins cluster into adhesive structures with various morphologies in nonepithelial cells. Immunofluorescence methods were used to detect integrin-containing adhesive structures (green) on cultured cells: (a) focal adhesions and (b) 3-D adhesions on the surfaces of human fibroblasts. Cells were grown (a) directly on the flat surface of a culture dish or (b) on a three-dimensional matrix of ECM components. The shape, distribution, and composition of the integrin-based adhesions formed by cells vary depending on the cells' environment.

Cell Biol*. **2**(11):793–805; permission conveyed through Copyright Clearance Center, Inc. Part (b) Kenneth Yamada and Edna Cukierman.]

Integrin-containing adhesive structures are dynamic due to ongoing import, export, or covalent modification of their components, and each contains dozens of intracellular adapter and associated proteins. These adhesive structures may in some cases assemble due to the formation of phase-separated biomolecular condensates

(see Chapter 3) in which each component has the potential of binding directly to many other components. The hundreds of such proteins identified to date have the potential to engage in many hundreds of distinct protein-protein interactions that may be subject to regulation. For example, binding sites generated by phosphorylation of integrin and its associated proteins, as well as by generation of phosphorylated derivatives of phosphatidylinositol in the adjacent membrane, recruit additional proteins into and can also cause release of some proteins from these multiprotein complexes. A tightly controlled choreography of internal signals, contributions of other signaling pathways such as those involving receptor tyrosine kinases (see Figure 20-8), and external signals (such as the composition and rigidity of the ECM) regulates these complexes. Together, they help define the precise composition and activity of the integrin multiprotein complex and the consequent influence that it has on cellular structure and activity (outside-in effect) as well as the influence of the cellular actin cytoskeleton on the ECM (inside-out effect). The adhesive structures can be stable and substantially contribute to the architecture of a tissue. They can also be transient. For example, the dynamic formation and dissolution of adhesive structures can result in cells grabbing onto the ECM for traction, exerting force to move relative to the adhesion site, and then disassembling to release the cell, permitting net movement as cells crawl through adjacent tissue.

Although found in many nonepithelial cells, integrin-containing adhesive structures have been studied most frequently in fibroblasts

grown in cell culture on flat glass or plastic surfaces called *substrata*. These conditions only poorly approximate the three-dimensional ECM environment that normally surrounds such cells in vivo. When fibroblasts are cultured in three-dimensional ECMs derived from cells or tissues, they form adhesions to the three-dimensional ECM substratum, called *3-D adhesions*. These structures differ somewhat in composition, shape, distribution, and activity from the focal or fibrillar adhesions seen in cells growing on the flat substrata typically used in cell culture experiments (see Figure 20-38). Cultured fibroblasts in three-dimensional ECMs have anchoring junctions that display greater adhesion and mobility, increased rates of cell proliferation, and spindle-shaped morphologies more like those of fibroblasts in tissues than do cells cultured on hard, flat surfaces. These and other observations indicate that the topological, compositional, and mechanical properties of the ECM all play a role in controlling the shape and activity of a cell, due at least in part to integrin-mediated bridging of the ECM to intracellular molecules. Tissue-specific differences in these ECM characteristics probably contribute to the tissue-specific properties of cells.

The importance of the three-dimensional environment of cells has been highlighted by cell-culture studies of the morphogenesis, functioning, and stability of specialized milk-producing mammary epithelial cells and their cancerous transformed counterparts. For example, the three-dimensional ECM-dependent outside-in signaling mediated by integrins influences the epidermal growth

factor–tyrosine kinase receptor signaling system, and vice versa. The three- dimensional ECM also permits the mammary epithelial cells to generate in vivo–like circular epithelial structures, called *acini*, which secrete the major protein constituents of milk. The use of such three-dimensional ECM cell culture systems permits more realistic comparisons of the responses of normal and cancer cells to potential chemotherapeutic agents. Analogous systems employing both natural and synthetic three-dimensional ECMs are being developed to provide more in vivo–like conditions to study other complex tissues and organs, such as the liver. In the presence of the appropriate ECM, many types of 3-D, organ-like tissues called *organoids*, similar to those in intact organisms, can now be generated from self-organizing, pluripotent or adult stem cells (see Chapters 4 and 22).

Regulation of Integrin-Mediated Adhesion and Signaling Controls Cell Function and Movement

Cells can exquisitely control the strength of integrin-mediated cell-matrix interactions by regulating integrin's expression levels, ligand-binding activities, or both. Such regulation is critical to the role of these interactions in cell migration and other functions involving cell movement.

Integrin Binding

Integrin binding to ECM and neighboring cells can influence the developmental fate of cells, determining the type of cell into which a progenitor cell will differentiate (see Chapter 22). Integrins participate in cells sensing the mechanical characteristics of their environments, such as the rigidity of the ECM, and responding appropriately.

Most integrins can exist in at least three conformations. In the first, inactive state (*bent closed* conformation, Figure 20-39a, *left*), the closely apposed extracellular domains of the αβ heterodimer are bent over, placing the ligand-binding site — located at the interface of the propeller (α chain) and βA (β chain) domains — near the plasma membrane and distant from the ECM. In the bent closed conformation, there is only low-affinity ligand binding and the transmembrane domains and cytoplasmic C-terminal tails of the two subunits are closely bound together. In the second, partially active state, the transmembrane and cytoplasmic domains of the α and β chains at least partially separate and the extracellular domains partially straighten into an *extended closed* conformation in which the ligand-binding site is projected farther away from the cell surface and assumes an intermediate affinity for ligands, such as a variety of ECM proteins (Figure 20-39a, *center*). In the third, fully active, *extended open* conformation, tension on the protein fully extends the extracellular domain of the β chain and confers high affinity ligand binding that can be as much as 4000-fold tighter than

binding to the bent closed conformation (Figure 20-39a, *right*). The changes in the conformations of integrin's cytoplasmic tails can influence the binding of intracellular adaptor proteins. For example, two of integrin's cytoplasmic adaptor proteins, talin and kindlin, can bind to short sequence motifs in the cytoplasmic tail of the β chain when it is separated from the tail of the α chain in the extended closed and open forms, but not when these sites are blocked in the bent closed form (see Figure 20-39a).

EXPERIMENTAL FIGURE 20-39 The three conformations of integrins. (a) Most integrins can be in one of three interconvertible conformations: inactive, low affinity for extracellular ligands (bent closed, *left*); partially active, intermediate

affinity (extended closed, *center*); and fully active, high affinity (extended open, *right*). Tension across the integrin due to pulling by either its extracellular ligand or intracellular binding partners drives the integrin into the extended open conformation. The extracellular ligand binding site is at the interface of the propeller domain on the α chain and the βA domain on the β chain. The cytoplasmic domain of the β chain has binding sites for intracellular adaptor proteins, e.g., talin and kindlin (green and yellow ovals, respectively). These sites are inaccessible (cryptic) in the bent closed form, but accessible in the extended forms due to separation of the transmembrane and cytoplasmic domains of the α and β chains (indicated by double-headed arrow). (b) Single inactive (bent closed) integrin αIIbβ3 molecules (*left*) were incorporated into phospholipid nanodiscs (small bilayers in which the extracellular and cytoplasmic domains of the integrin are exposed to a buffer), and the integrin-binding and activating head domain of the adapter protein talin was added to some of these preparations (*right*). Multiple electron microscopic images of individual nanodiscs were collected and averaged. Phospholipid nanodiscs are indicated by dashed white circles, and the heights of the integrin extracellular regions that extend above the nanodiscs are indicated by brackets. Binding of talin's head domain to the cytoplasmic domain of the β chain traps the integrins in the extended closed conformation.

[Part (a) Information from J. Wang et al., 2019, *Nat. Commun.* **10**:5481. Part (b) F. Ye et al., 2010, *J. Cell Biol.* **188**(1):157–173, Fig. 7; https://doi.org/10:1083/jcb.200908045.]

One helpful way to think about these three forms of integrins is that there is an equilibrium distribution of integrin molecules in all three conformations (they can readily interconvert). When the integrin is bound to neither extracellular ligands (e.g., ECM) nor intracellular partners (e.g., talin), the large majority of unbound integrin molecules is in the bent, inactive conformation. Binding of extracellular ligands to the extended conformations traps more of

the integrins in the extended conformations than in the absence of the ligands (shifts the equilibrium distribution) and thus facilitates the binding of intracellular adaptor proteins such as talin or kindlin to the now accessible sites in the β chain's cytoplasmic domain. Similarly, binding of intracellular adaptors to the extended conformations increases the fraction of integrin molecules in extended conformations (again, a shift in the equilibrium distribution) and facilitates extracellular ligand binding to the intermediate and high-affinity ligand-binding sites. Thus binding of ligands to integrins on either side of the membrane can increase binding on the other side.

The structural features of integrin's α and β subunits that permit them to adopt the bent and extended conformations have been preserved through metazoan evolution, indicating their importance for integrin function. Indeed, these three conformations provide an attractive explanation for the ability of integrins to mediate outside-in and inside-out signaling. The binding to the integrin's extracellular ligand-binding site of certain ECM molecules or CAMs on other cells would shift the distribution of conformations and thus result in more integrins in the extended closed or extended open forms with at least partially separated cytoplasmic tails. Intracellular adapter proteins could recognize the separation of the tails and, as a result, bind to the tails. Integrin-binding-dependent changes in these adapters can then alter the cytoskeleton and activate or inhibit intracellular signaling pathways. Conversely, changes in the metabolic or signaling state of the cells could cause

intracellular adapters to bind to or dissociate from the cytoplasmic tails of the integrins and thus alter the distribution of integrin conformations. Such binding can force the tails either to separate or to associate (see Figure 20-39a). As a consequence, a greater fraction of the integrins would be either in the bent closed (inactive), extended closed (partially active), or extended open (fully active) conformations, thereby altering their interactions with the ECM or with other cells. Indeed, in vitro EM studies of purified integrins reconstituted individually into lipid bilayer nanodiscs show that binding of the head domain of the adapter/mechanosensor protein talin (described in detail below; see Figure 20-40) to the cytoplasmic tail of integrin's β chain is sufficient to partially activate integrin, inducing a straightening of the bent closed conformation into the extended closed form (see Figure 20-39b).

We can see an example of integrins mediating intracellular-extracellular communication in the initial formation of focal adhesions in Figure 20-40. Although there are many intracellular proteins involved, this figure focuses on talin, actin, and vinculin. Figure 20-40a shows a model of an active conformation of talin and Figures 20-40b and c show some of the key steps associated with integrin/talin-mediated inside-out signaling. In the absence of stimulation, most of the talin in the cytoplasm is condensed into an inactive, autoinhibited, compact structure in which interdomain binding sterically blocks talin binding to some of its many partners, including integrins and actin (see Figure 20-40b, *lower left*).

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

FIGURE 20-40 Talin- and integrin-mediated intracellular-extracellular communication. (a) *Top:* A hypothetical model of an elongated, active conformation of a talin monomer based on structures of fragments of the intact protein with secondary structures illustrated as tubes (α helices) and ribbons with arrowheads (β sheets). The N-terminal "head" domain (four globular subdomains) is connected by an apparently unstructured domain to a rod domain that comprises 13 α-helical bundles (4 or 5 helices per bundle), 9 of which contain either 1 or 2 helices (red, total of 11) that are cryptic binding sites for the protein vinculin. Some bundles also contain cryptic actin-binding sites. These helices can only bind vinculin when exposed by unfolding (see Figure 20-9b). There is a single α helix at the extreme C-terminus that is a dimerization domain. *Bottom:* A cartoon model. Head subdomains = gray ovals; rod domain bundles = colored capsules; and dimerization domain = narrow rectangle. (b) Intracellular signaling induces the translocation of inactive talin in the cytoplasm to the plasma membrane and its unfolding/activation (steps **1** and **2**). The binding of activated talin to integrin's β chain cytoplasmic domain stabilizes integrin's extended closed conformation, promoting binding to the ECM (step **3**). The unfurled talin homodimerizes and binds several proteins, including actin filaments that bind via talin's C-terminal dimerization domain (shown) and several other sites (not shown) (step **4**). The actin filaments exert force (step **5**), generating tension across the ECM/integrin/talin complex. This tension converts the integrin into the fully active, extended open form (step **6**). (c) Subsequent steps illustrated for the region outlined in the light gray dashed box in part (b) are shown. Additional force unfolds one or more of talin's helical bundles (step **7**), exposing cryptic binding site(s) (red helix) that recruit vinculin and other proteins, including more actin (steps **8** and **9**), resulting in growth of the focal adhesion.

Intracellular signaling can induce the translocation of talin to the inner leaflet of the plasma membrane, for example, by generating polyphosphoinositides to which globular subdomains in talin's head

domain can bind and by small GTP-binding proteins (Figure 20-40b, steps **1** and **2**). In steps **2** and **3**, the compact autoinhibited rod domain unfolds into the active conformation (see Figure 20-40a) and a portion of the head domain binds to the cytoplasmic domain of integrin's β chain. Talin binds to integrin's β chain cytoplasmic domain when the transmembrane and cytoplasmic domains of integrin's α and β chains at least partly separate in the extended closed conformation. In this conformation integrin binds to the ECM with intermediate affinity (see Figure 20-39). The order of these events is not well established. The C-terminal dimerization domain in the unfurled, extended, and active talin mediates homodimerization, and actin filaments can bind to several sites in the rod domains in the dimeric talin, including the C-terminal dimerization domain (step **4**, also see Figure 20-40a). Other binding partners can also bind to the unfurled, active talin. Additional signaling steps mediated by the partially active, extended closed integrin (e.g., activation of kinases, such as focal adhesion kinase and scr-like kinases) induce formin-mediated actin filament formation and myosin engagement with actin filaments to exert force on the talin (step **5**, also see Chapter 17). As a consequence, tension develops in the ECM-bound integrin/talin complex, converting the integrin into the fully active, extended open form (step **6**).

Additional force applied to the integrin/talin complex, exerted either from the cytoplasm (e.g., actin filaments and myosin) or the ECM, can pull apart the α-helical bundles in talin (Figure 20-40c, step **7**),

exposing cryptic vinculin binding sites (red helix). The greater the force, the more α-helical bundles in talin are opened and the more vinculin, actin, and other proteins are recruited to the integrin/talin complex. Vinculin binding to exposed sites on talin can then recruit other proteins, such as actin filaments (steps **8** and **9**). The unfolded bundles can readily refold when the force is reduced. Strikingly, the more rigid the structure of the ECM, the greater the tension across the integrin/talin complex and the larger and stronger the adhesion. During steps **3**–**9**, integrins begin to cluster and the focal adhesion can continue to grow and form a mature focal adhesion that firmly attaches the cell to the ECM. Alternatively, the multiprotein adhesion complex can dissociate with inactivation of the integrins and other components, in part due to recruitment of inhibitory proteins.

Studies suggest that the efficient activation of integrins in intact cells may also require the participation of another class of adapter proteins called *kindlins*, which bind to a distinct site on the cytoplasmic tail of integrin's β chain (see Figure 20-39a). Kindlin plays a key role in the integrin- and microfibril-mediated activation of TGF-β (inside-out signaling involving elastic fibers and their microfibril-associated protein LTBP, described earlier) and other pathways of integrin-mediated signaling, such as recruitment of branched actin networks in lamellipodia (see Chapter 17).

Platelet function, discussed in more detail below, provides a good example of how cell-matrix interactions are modulated by control of integrin-binding activity. Platelets are cell fragments that circulate in the blood and clump together with ECM molecules to form a blood clot. In its basal state, the αIIbβ3 integrin present on the plasma membranes of platelets cannot bind tightly to its protein ligands (including fibrinogen and fibronectin), all of which participate in the formation of a blood clot, because it is in the inactive (bent closed) conformation. During clot formation, platelets are activated by binding to ECM proteins such as collagen and a large protein called *von Willabrand factor* that, through binding to receptors, generate intracellular signals. Platelets may also be activated by ADP or the clotting enzyme thrombin. These signals induce changes in signaling pathways within the platelet that result in an activating conformational change in the platelet's αIIbβ3 integrin. As a consequence, this integrin can bind tightly to extracellular clotting proteins and participate in clot formation. People with genetic defects in the β3 integrin subunit are prone to excessive bleeding, attesting to the role of the αIIbβ3 integrin in the formation of blood clots (see Table 20-4).

Integrin Expression

The attachment of cells to ECM components can also be modulated by altering the number of integrin molecules exposed on the cell surface. The α4β1 integrin, which is found on many hematopoietic

cells, offers an example of this regulatory mechanism. For these hematopoietic cells to proliferate and differentiate, they must be attached to fibronectin synthesized by supportive (stromal) cells in the bone marrow. The α4β1 integrin on hematopoietic cells binds to a Glu-Ile-Leu-Asp-Val (EILDV) sequence in fibronectin in the ECM, thereby anchoring the cells to the matrix. This integrin also binds to a sequence in a CAM called *vascular CAM-1 (VCAM-1)*, which is present on stromal cells of the bone marrow. Thus hematopoietic cells directly contact the stromal cells as well as the ECM. Late in their differentiation, hematopoietic cells decrease their expression of this integrin; the resulting reduction in the number of α4β1 integrin molecules on the cell surface is thought to allow mature blood cells to detach from the ECM and stromal cells in the bone marrow and enter the circulation.

Connections Between the ECM and Cytoskeleton Are Defective in Muscular Dystrophy

The importance of the adhesion receptor–mediated linkage between ECM components and the cytoskeleton is highlighted by a set of hereditary muscle-wasting diseases, collectively called *muscular dystrophies*. Duchenne muscular dystrophy (DMD), the most common type, is a sex-linked disorder, affecting 1 in 3300 boys, that results in cardiac or respiratory failure, usually in the late teens

or early twenties. The first clue to understanding the molecular basis of this disease came from the discovery that people with DMD carry mutations in the gene encoding a protein named *dystrophin*. This very large protein was found to be a cytosolic adapter protein that contains a long central rodlike region with 24 repeats of a three-α-helix bundle, flanked by an N-terminal F-actin-binding domain and C-terminal domains that bind to several plasma membrane and cytoplasmic proteins (Figure 20-41). Several of the central repeats also bind to F-actin and dystrophin links the actin filaments to an adhesion receptor called *dystroglycan* (see Figure 20-41). It is noteworthy that when dystrophin is subjected to tension some of its α-helical repeats unfold and the protein substantially lengthens, a feature somewhat reminiscent of the force-induced unfolding of talin (see Figure 20-40). However, a role for dystrophin in mechanotransduction has not been established.

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

FIGURE 20-41 The dystrophin glycoprotein complex (DGC) in skeletal muscle cells. This schematic model shows that the DGC comprises three subcomplexes: the α, β-Dystroglycan subcomplex; the integral membrane protein sarcospan and the sarcoglycan complex; and the cytosolic adapter subcomplex comprising dystrophin, other adapter proteins, and signaling molecules. Through its *O*-linked matriglycan sugars (see Figure 20-31c), α-dystroglycan binds to LG-domain-containing components of the basal lamina, such as laminin and the GAG-containing proteoglycans perlecan and agrin. Dystrophin — the protein that is defective in DMD — links β-dystroglycan to the actin cytoskeleton, and α-dystrobrevin links dystrophin to the sarcoglycan complex and sarcospan. Neuronal nitric oxide synthase (nNOS), which produces the gaseous signaling molecule nitric oxide, binds to dystrophin via the adaptors called *syntrophins*. See S. J. Winder, 2001, *Trends Biochem. Sci.* **26**:118–124; D. E. Michele and K. P. Campbell, 2003, *J. Biol. Chem.* **278**(18):15457–15460; T. Yoshida-Moriguchi and K. P. Campbell, 2015,

Glycobiology **25**(7):702–713; and Y. M. Kobayashi and K. P. Campbell, 2012, Chapter 66, "Skeletal Muscle Dystrophin-Glycoprotein Complex and Muscular Dystrophy," in J. A. Hill and E. N. Olson, eds., *Muscle*, vol. 2, Elsevier/Academic Press.

Dystroglycan is a heterodimeric (α and β subunits) cell-surface glycoprotein (see Figure 20-41). As noted in Section 20.4, about three of the more than 20 *O*-linked oligosaccharide chains in dystroglycan's α subunit are directly linked to the hydroxyl group via a mannose sugar that is phosphorylated (see Figure 20-31c). A phosphorylated hexasaccharide connects the phosphorylated mannose to a GAG-like polymer of xylose–glucuronic acid disaccharides called **matriglycan**. One key enzyme in the synthesis of the matriglycan oligosaccharide that is located in the Golgi complex is called *LARGE*.

The *O*-linked matriglycan binds to various components of the basal lamina, including the multi-adhesive matrix protein laminin (see Figures 20-25 and 20-41) and the proteoglycans perlecan and agrin. The neurexins, a family of cell-surface adhesion molecules expressed by neurons, also bind matriglycan. All of these bind to matriglycan via LG domains (see Figure 20-41).

Dystroglycan's transmembrane β subunit associates with a group of integral membrane proteins called the *sarcoglycan complex* and *sarcospan*, while its cytosolic domain binds directly to dystrophin and directly or indirectly to other adapter and signaling proteins

(see Figure 20-41). Sarcospan is a tetraspanin, as are claudin and occludin in tight junctions (see Figure 20-18b). The resulting large, heteromeric assemblage, the *dystrophin glycoprotein complex (DGC)*, links the ECM to the actin cytoskeleton. Binding to laminin in the basal lamina leads to a cluster of DGCs on the cell surface. The DGC is associated with signaling pathways within muscle and other types of cells. For instance, the signaling enzyme neuronal nitric oxide synthase (nNOS) is associated through syntrophin with the DGC in skeletal muscle. The rise in intracellular Ca^{2+} during muscle contraction activates nNOS to produce nitric oxide (NO), a signaling molecule that diffuses into smooth muscle cells surrounding nearby blood vessels. NO promotes smooth muscle relaxation, leading to a local rise in the flow of blood supplying nutrients and oxygen to the active skeletal muscle. Heart (cardiac) muscle contraction may be influenced by similar NOS-syntrophin interactions.

Mutations in the genes encoding dystrophin, other DGC components, laminin, or the multiple enzymes that mediate the addition of matriglycan to dystroglycan can all disrupt the DGC-mediated link between the exterior and the interior of muscle cells and cause muscular dystrophies. In addition, dystroglycan mutations have been shown to greatly reduce the clustering of acetylcholine receptors on muscle cells at the neuromuscular junctions, which is also dependent on the basal lamina proteins laminin and agrin. These and possibly other effects of DGC defects apparently lead to a cumulative loss of the mechanical stability of

muscle cells as they undergo contraction and relaxation, resulting in deterioration of the cells and muscular dystrophy.

Dystroglycan is an elegant and medically relevant example of the intricate networks of connectivity in cell biology. While originally discovered in the context of studying muscular dystrophy, it was later shown to be expressed in nonmuscle cells and, through its binding to laminin, to play a key role in the assembly and stability of at least some basement membranes. The extent of glycosylation of dystroglycan, such as the length of the matriglycan repeats, varies in different tissues, suggesting that alterations in its glycosylation regulate function. Dystroglycan is essential for normal development, including the proper functioning of some neuronal synapses (see Chapter 23). Additional studies led to its identification as a cell-surface receptor for the virus that causes the frequently fatal human disease Lassa fever and other related viruses, all of which bind via matriglycan. Furthermore, dystroglycan is the receptor on specialized cells in the nervous system — Schwann cells — to which binds the pathogenic bacterium *Mycobacterium leprae*, the organism that causes leprosy. ■

IgCAMs Mediate Cell-Cell Adhesion in Neural and Other Tissues

Numerous transmembrane proteins characterized by the presence of multiple immunoglobulin domains in their extracellular regions constitute the immunoglobulin (Ig) superfamily of CAMs, or *IgCAMs* (e.g., see NCAM in Figure 20-2). The Ig domain is a common protein domain, containing 70–110 residues. It was first identified in antibodies, the antigen-binding immunoglobulins (see Chapter 24), but has a much older evolutionary origin in CAMs. The human, *Drosophila*, and *C. elegans* genomes include about 765, 150, and 64 genes, respectively, that encode proteins containing Ig domains. Immunoglobulin domains are found in a wide variety of cell-surface proteins, including the T-cell receptors produced by lymphocytes and many proteins that take part in adhesive interactions. Among the IgCAMs are neural CAMs; intercellular CAMs (ICAMs), which function in the movement of leukocytes into tissues; and junction adhesion molecules (JAMs), which are present in tight junctions (see Figure 20-18b).

As their name implies, neural CAMs are of particular importance in neural tissues. One type, the NCAMs, primarily mediate homophilic interactions. First expressed during morphogenesis, NCAMs play an important role in the differentiation of muscle cells, glial cells, and neurons. Their role in cell adhesion has been directly demonstrated by the inhibition of adhesion with anti-NCAM antibodies. Numerous NCAM isoforms, encoded by a single gene, are generated by alternative mRNA splicing and by differences in glycosylation. Other neural CAMs (e.g., L1-CAM) are encoded by different genes. In

humans, mutations in different parts of the L1-CAM gene cause various neuropathologies (e.g., mental retardation, congenital hydrocephalus, and spasticity).

An NCAM comprises an extracellular region with five Ig domains and two fibronectin type III domains, a single membrane-spanning segment, and a cytosolic segment that interacts with the cytoskeleton (see Figure 20-2). In contrast, the extracellular region of L1-CAM has six Ig domains and four fibronectin type III domains. As with cadherins, cis (on the same cell) interactions and trans (intercellular) interactions probably play key roles in IgCAM-mediated adhesion (see Figure 20-3); however, adhesion mediated by IgCAMs is Ca^{2+} independent.

Leukocyte Movement into Tissues Is Orchestrated by a Precisely Timed Sequence of Adhesive Interactions

In adult organisms, several types of white blood cells (leukocytes) participate in defense against infection caused by bacteria and viruses and respond to tissue damage due to trauma or inflammation. To fight infection and clear away damaged tissue, these cells must move rapidly from the blood, where they circulate as unattached, relatively quiescent cells, into the underlying tissue at sites of infection, inflammation, or damage. We know a great deal

about the movement into tissue, termed *extravasation*, of four types of leukocytes: neutrophils, which release several antibacterial proteins; monocytes, the precursors of macrophages, which can engulf and destroy foreign particles; and T and B lymphocytes, the antigen-recognizing cells of the immune system (see Chapter 24).

Extravasation requires the successive formation and breakage of cell-cell contacts between leukocytes in the blood and endothelial cells lining the vessels. Some of these contacts are mediated by **selectins**, a family of CAMs that mediate leukocyte–vascular endothelium interactions. Endothelial cells express *P-* and *E-selectins* on their blood-facing surfaces, activated platelets express P-selectin, and leukocytes express *L-selectin*. All selectins contain a Ca^{2+}-dependent *lectin domain*, which is located at the distal end of the extracellular region of the molecule and recognizes particular sugars in glycoproteins or glycolipids (see Figure 20-2). For example, the primary ligand for P- and E-selectins is an oligosaccharide called the *sialyl Lewis-x antigen*, a part of longer oligosaccharides present in abundance on leukocyte glycoproteins and glycolipids.

Figure 20-42 illustrates the basic sequence of cell-cell interactions leading to the extravasation of leukocytes. Various inflammatory signals released in areas of infection or inflammation first cause activation of the vascular endothelium. P-selectin exposed on the surfaces of activated endothelial cells mediates the weak adhesion of passing leukocytes. Because of the force of the blood flow and the

rapid “on” and “off” rates of P-selectin binding to its ligands, these bound leukocytes are slowed, but not stopped, and literally roll along the surface of the endothelium. Among the signals that promote activation of the endothelium are chemokines, a group of small, secreted proteins (8–12 kDa) produced by a wide variety of cells, including endothelial cells and leukocytes.

FIGURE 20-42 Endothelium-leukocyte interactions: activation, binding, rolling, and extravasation. Step 1: In the absence of inflammation or infection, leukocytes and endothelial cells lining blood vessels are in a resting state and not interacting. Step 2: Inflammatory signals released only in areas of inflammation, infection, or both activate resting endothelial cells, resulting in the movement of vesicle-sequestered selectins to the cell surface. The exposed selectins mediate weak binding of leukocytes by interacting with carbohydrate ligands on leukocytes. Blood flow forces the loosely bound leukocytes to roll along the endothelial surface of the blood vessel (curved arrow). Activation of the endothelium also causes synthesis of platelet-activating factor (PAF) and ICAM-1, both expressed on the endothelial cell surface. PAF and other, usually secreted, activators, including chemokines, then induce changes in the shapes of the leukocytes and activation of leukocyte integrins such as αLβ2, which is expressed by T lymphocytes (step 3). The subsequent tight binding between activated integrins on leukocytes and CAMs on the endothelium (e.g., ICAM-2 and ICAM-1) results in firm adhesion (step 4) and subsequent movement (extravasation) into the underlying tissue (step 5). See R. O. Hynes and A. D. Lander, 1992, *Cell* **68**:303.

For tight adhesion to occur between activated endothelial cells and leukocytes, β2-containing integrins on the surfaces of the leukocytes must be activated indirectly by chemokines or by other local activation signals such as *platelet-activating factor (PAF)*. Platelet-activating factor is unusual in that it is a phospholipid rather than a protein; it is exposed on the surfaces of activated endothelial cells at the same time that P-selectin is exposed. The binding of PAF or other activators to their G protein–coupled receptors on leukocytes leads to activation of the leukocyte integrins (see Figure 20-39). These activated integrins then bind to distinct IgCAMs on the surfaces of endothelial cells. These IgCAMs include ICAM-2, which is expressed constitutively, and ICAM-1, whose synthesis is induced by activation. ICAM-1 does not usually contribute substantially to leukocyte adhesion to endothelial cells immediately after activation, but rather participates at later times in cases of chronic inflammation. The tight adhesion mediated by these Ca^{2+}-independent integrin-ICAM interactions leads to the cessation of rolling and to the spreading of leukocytes on the surface of the endothelium; soon the adhered cells move between adjacent endothelial cells and into the underlying tissue. The extravasation step itself (also called *transmigration* or *diapedesis*; step **5** in Figure 20-42) requires the dissociation of otherwise stable adhesive interactions between endothelial cells that are primarily mediated by the CAM VE-cadherin. There is general agreement that the leukocyte interactions with endothelial cells mediated by CAMs

initiate outside-in signaling in the endothelial cells that involves phosphorylation, activation of small GTPases, and an increase in cytosolic calcium concentration. These signals weaken or disrupt VE-cadherin-mediated inter-endothelial-cell adherens junctions and increase actin-myosin contraction, which pulls the endothelial cells apart, thus permitting the paracellular, amoeboid movement of the leukocyte between adjacent endothelial cells that is responsible for most extravasation.

The selective adhesion of leukocytes to the endothelium near sites of infection or inflammation thus depends on the sequential appearance and activation of several different CAMs on the surfaces of the interacting cells. Different types of leukocytes express different integrins, though all contain the β2 subunit. Nonetheless, all leukocytes move into tissues by the general mechanism depicted in Figure 20-42.

Many of the CAMs used to direct leukocyte adhesion are shared among different types of leukocytes and target tissues, yet often only a particular type of leukocyte is directed to a particular tissue. How is this specificity achieved? A three-step model has been proposed to account for the cell-type specificity of such leukocyte-endothelium interactions. First, endothelial activation promotes initial relatively weak, transient, and reversible binding (e.g., the interaction of selectins and their carbohydrate ligands). Without additional local activation signals, the leukocyte will quickly move on. Second, cells in the immediate vicinity of the site of infection or inflammation

release or express chemical signals such as chemokines and PAFs that activate only special subsets of the transiently attached leukocytes, depending on the types of chemokine receptors those leukocytes express. Third, additional activation-dependent CAMs (e.g., integrins) engage their binding partners, leading to strong, sustained adhesion. Only if the proper combination of CAMs, binding partners, and activation signals are engaged together with the appropriate timing at a specific site will a given leukocyte adhere strongly. Such combinatorial diversity and cross talk allows a small set of CAMs to serve diverse functions throughout the body — a good example of biological efficiency.

Leukocyte-adhesion deficiency is caused by a genetic defect in the synthesis of the integrin β2 subunit. People with this disorder are susceptible to repeated bacterial infections because their leukocytes cannot extravasate properly and thus cannot effectively fight infection within a tissue.

Some pathogenic viruses have evolved mechanisms to exploit cell-surface proteins that participate in the normal response to inflammation. For example, many of the RNA viruses that cause the common cold (rhinoviruses) bind to and enter cells through ICAM-1, and chemokine receptors can be important entry sites for human immunodeficiency virus (HIV), the cause of AIDS. Integrins appear to participate in the binding or internalization of a wide variety of viruses, including reoviruses (which cause fever and gastroenteritis, especially in infants), adenoviruses (which cause conjunctivitis and acute respiratory disease), and foot-and-mouth disease virus (which causes fever in cattle and pigs). ■

KEY CONCEPTS OF SECTION 20.5

Adhesive Interactions in Motile and Nonmotile Cells

- Many cells have integrin-containing clusters of proteins (e.g., focal adhesions, 3-D adhesions, podosomes) that physically and functionally connect cells to the ECM and facilitate inside-out and outside-in signaling.
- Via interaction with integrins, the three-dimensional structure of the ECM surrounding a cell can profoundly influence the behavior of the cell.
- Integrins exist in at least three conformations (bent closed, extended closed, extended open) that differ in their affinity for ligands and in their interactions with cytosolic adapter proteins and extracellular ligands (see Figure 20-39). Switching between these conformations depends, in part, on the application of mechanical force and allows regulation of integrin activity, which is important for control of cell adhesion and movements. Talin, one of many cytoplasmic adaptors that interact with integrins, can function as a mechanosensor. Talin can mediate integrin's interactions with the cytoskeleton and thus its switching between conformational and functional states.
- Dystroglycan, an adhesion receptor, forms a large complex with dystrophin, other adapter proteins, and signaling molecules (see Figure 20-41). This complex links the actin cytoskeleton to the surrounding ECM, providing mechanical stability to muscle.

Mutations in various components of this complex cause different types of muscular dystrophy.

- Neural cell-adhesion molecules, which belong to the immunoglobulin (Ig) family of CAMs, mediate Ca^{2+}- independent cell-cell adhesion in neural and other tissues.
- The combinatorial and sequential interaction of several types of CAMs (e.g., selectins, integrins, and ICAMs) is critical for the specific adhesion of different types of leukocytes to endothelial cells in response to local signals induced by infection or inflammation (see Figure 20-42).

20.6 Plant Tissues

We turn now to the assembly of plant cells into tissues. The overall structural organization of plants is generally simpler than that of animals. For instance, plants have only four broad types of cells, which in mature plants form four basic classes of tissue: *dermal tissue* interacts with the environment, *vascular tissue* transports water and dissolved substances such as sugars and ions, space-filling *ground tissue* constitutes the major sites of metabolism, and *sporogenous tissue* forms the reproductive organs. Plant tissues are organized into just four main organ systems: *stems* have support and transport functions, *roots* provide anchorage and absorb and store nutrients, *leaves* are the sites of photosynthesis, and *flowers* enclose the reproductive structures. Thus at the cell, tissue, and organ levels, plants are generally less complex than most animals.

Moreover, unlike animals, plants do not replace or repair old or damaged cells or tissues; they simply grow new organs. Indeed, the developmental fate of any given plant cell is primarily based on its position in the organism rather than on its lineage, whereas both are important in animals (see Chapter 22). In both plants and animals, a cell's direct communication with its neighbors is important. Most importantly for this chapter, and in contrast with animals, few cells in plants contact one another directly through molecules incorporated into their plasma membranes. Instead, plant cells are typically surrounded by a rigid cell wall that contacts the cell walls

of adjacent cells (Figure 20-43a). Also in contrast with animal cells, a plant cell rarely changes its position in the organism relative to other cells. These features of plants and their organization have determined the distinctive molecular mechanisms by which plant cells are incorporated into tissues and communicate with one another.

FIGURE 20-43 Structure of the plant cell wall. (a) Overview of the organization of a typical plant cell, in which the organelle-filled cell with its plasma membrane is surrounded by a well-defined extracellular matrix called the *cell wall*. (b) Schematic representation of the cell wall of an onion. Cellulose (highly ordered glucose polymers) and hemicellulose (amorphous polysaccharide) are arranged into at least three layers in a matrix of the polysaccharide pectin and glycoproteins. The sizes of the polymers and their separations are drawn to scale. To simplify the diagram, most of the hemicellulose cross-links and other matrix constituents (e.g., glycoproteins such as extensin, complex organic polymers called *lignins*) are not shown. (c) Quick-freeze deep-etch electron micrograph of the cell wall of a garden pea in which some of the pectin molecules were removed by chemical treatment. The abundant thicker fibers are cellulose microfibrils, and the thinner fibers are hemicellulose cross-links (red arrowheads).

During Elongation Growth in Pea Epicotyl," *Plant Cell Physiol*. 2000, **41**(4):486–494; permission conveyed through Copyright Clearance Center, Inc.]

The Plant Cell Wall, a Plant's ECM, Is a Laminate of Cellulose Fibrils in a Matrix of Polysaccharides and Glycoproteins

The plant **cell wall**, an extracellular matrix that is mainly composed of polysaccharides and is about 0.2 μm thick, completely coats the outside of the plant cell's plasma membrane. This structure serves some of the same functions as the ECM produced by animal cells, even though the two structures are composed of entirely different macromolecules and have a different organization. About 1000 genes in the plant *Arabidopsis*, a small flowering plant (also called "thale cress"; see Chapters 1 and 7), are devoted to the synthesis and functioning of its cell wall, including approximately 414 glycosyltransferase genes, which encode enzymes that transfer specific sugar residues to proteins or polysaccharides, and more than 316 glycosyl hydrolase genes, which encode enzymes that degrade sugar containing polymers. Similar to animal ECMs, the plant cell wall organizes cells into tissues, signals a plant cell to grow and divide, and controls the shapes of plant organs (morphogenesis). It is a dynamic structure that plays important roles in controlling the differentiation of plant cells during

embryogenesis and growth, and it provides a barrier to protect against pathogen infection. Just as the ECM helps define the shapes of animal cells, the cell wall defines the shapes of plant cells. When the cell wall is digested away from plant cells by hydrolytic enzymes, spherical cells enclosed by a plasma membrane are left.

Because a major function of the plant cell wall is to withstand the turgor pressure of the cell (between 14.5 and 435 pounds per square inch; as much as three orders of magnitude greater than in animal cells and about 13 times greater than in an automobile tire; see Chapter 11), the cell wall is built for lateral strength. It is arranged into layers of **cellulose** microfibrils: bundles of 18–36 parallel chains of extensively hydrogen-bonded, long (as much as 4 μm or greater), linear polymers of glucose in β glycosidic linkages. The cellulose microfibrils are embedded in a matrix composed of *pectin*, a negatively charged polymer of D-galacturonic acid and other monosaccharides, and *hemicellulose*, a short, highly branched polymer of several five- and six-carbon monosaccharides. The mechanical strength of the cell wall depends on cross-linking of the microfibrils by hemicellulose chains (Figure 20-43b, c). The layers of microfibrils prevent the cell wall from stretching laterally. Cellulose microfibrils are synthesized on the exoplasmic face of the plasma membrane from UDP-glucose and ADP-glucose formed in the cytosol. The polymerizing enzyme, called *cellulose synthase*, moves within the plane of the plasma membrane along tracks of intracellular microtubules as cellulose is formed, providing a

distinctive mechanism for intracellular-extracellular communication and ensuring that the cellulose microfibrils are oriented properly to permit cell wall, and thus whole-cell, growth.

Unlike cellulose, pectin and hemicellulose are synthesized in the Golgi complex and transported to the cell surface, where they form an interlinked network that helps bind the walls of adjacent cells to one another and cushions them. When purified, pectin binds water and forms a gel in the presence of Ca^{2+} and borate ions — hence the use of pectins in many processed foods. As much as 15 percent of the cell wall may be composed of *extensin*, a glycoprotein that contains abundant hydroxyproline and serine. Most of the hydroxyproline residues are linked to short chains of arabinose (a five-carbon monosaccharide), and the serine residues are linked to galactose. Carbohydrate accounts for about 65 percent of extensin by weight, and its protein backbone forms an extended rodlike helix with the hydroxyl or *O*-linked carbohydrates protruding outward. *Lignin* — a complex, insoluble polymer of phenolic residues — associates with cellulose and is a strengthening material. Like cartilage proteoglycans, lignin resists compression forces.

The cell wall is a selective filter whose permeability is controlled largely by pectins. Whereas water and ions diffuse freely across and through cell walls, the diffusion of large molecules, including proteins larger than 20 kDa, is limited. This limitation may explain why many plant hormones are small, water-soluble molecules,

which can diffuse across the cell wall and interact with receptors in the plasma membrane of plant cells.

Loosening of the Cell Wall Permits Plant Cell Growth

Because the cell wall surrounding a plant cell prevents it from expanding, the wall's structure must be loosened when the cell grows. The amount, type, and direction of plant-cell growth are regulated by small-molecule hormones called *auxins*. The auxin-induced weakening of the cell wall permits the expansion of the intracellular vacuole (see Figure 20-42a) by uptake of water, leading to elongation of the cell. We can grasp the magnitude of this phenomenon by considering that, if all cells in a redwood tree were reduced to the size of a typical liver cell, the tree would have a maximum height of only 1 meter, about a hundredfold less than normal.

The cell wall undergoes its greatest changes at the *meristem* in a root or shoot tip. Meristems are where cells divide and grow, as described in Chapter 22. Young meristematic cells are connected by thin, flexible *primary cell walls*, which can be loosened and stretched to allow subsequent cell elongation. Their major components are cellulose, pectin, and polysaccharides called *xyloglucans*. After cell elongation ceases, the cell wall is generally thickened, either by the

secretion of additional macromolecules into the primary wall or, more usually, by the formation of a *secondary cell wall* composed of several layers. Cellulose, lignin, and polysaccharides called *xylans* and *glucomannans* are the major components in secondary cell walls. In mature tissues such as the xylem — the tubes that conduct salts and water from the roots through the stems to the leaves — most of the cell eventually degenerates, leaving only the cell wall. The unique properties of wood and of plant fibers such as cotton are due to the molecular properties of the cell walls in the tissues of origin.

Plasmodesmata Directly Connect the Cytosols of Adjacent Cells

The presence of a cell wall separating cells in plants imposes barriers to cell-cell communication not faced by animals. One distinctive mechanism used by plant cells to communicate directly is specialized cell junctions called **plasmodesmata**, which are large tubes that extend through the cell wall (Figure 20-44) and were discovered in 1885. Like gap junctions, plasmodesmata can function as channels that directly connect the cytosol of a cell to that of an adjacent cell without a membrane barrier. Plasmodesmata appear to play an especially important role in protection from pathogens and in regulating the development of plant cells and tissues, as is

suggested by their ability to mediate intracellular movement of transcription factors and ribonuclear protein complexes.

FIGURE 20-44 Plasmodesmata. (a) Schematic model of plasmodesmata, showing the desmotubule, an extension of the endoplasmic reticulum (ER), and the annulus, a plasma-membrane-lined channel filled with cytosol that interconnects the cytosols of adjacent cells. The regulated deposition of a glucose polymer called *callose* in the extracellular spaces in the cell wall adjacent to the entrances of the channels has the potential to block intercellular transport through the plasmodesmata, apparently by forcing the closing of the channels by narrowing the annulus. (b) Electron micrographs of thin sections of a sugarcane leaf (brackets indicate individual plasmodesmata). *Left:* Longitudinal view, showing the ER and desmotubule running through each annulus. *Right:* Perpendicular cross-sectional views of plasmodesmata, each with its annulus, desmotubule, and cytoplasmic sleeve. (c) Cells from the plant *Arabidopsis* were grown in culture, frozen, and, while cold, fixed with glutaraldehyde and stained with osmium tetroxide and uranyl acetate. Multiple views of one plasmodesma were visualized by tilting the sample in an electron microscope and a three-dimensional tomographic model of the structure was computed. Shown is the electron micrograph of one view (black and white) with the colored model of its plasmodesma; plasmamembrane = yellow; ER and desmotubule membrane = blue; and spoke-like tethers connecting these membranes = red. The gap between the two membranes is the cytoplasmic sleeve..

Nicolas et al., 2017, "Architecture and Permeability of Post-Cytokinesis Plasmodesmata Lacking Cytoplasmic Sleeves." *Nature Plants* **3**:17082; permission conveyed through Copyright Clearance Center, Inc.]

Although plasmodesmata and gap junctions appear to resemble each other functionally with respect to forming channels for direct diffusion of molecules from one cell's cytosol to that of another,

their structures differ dramatically in two significant ways. First, in animal-cell gap junctions, the membranes of the connected cells are distinct, and the cytosols are connected by a protein-lined tube of connexon hemichannels (see Figure 20-21). In plant plasmodesmata (see Figure 20-44), the plasma membranes of the adjacent plant cells merge to form a continuous single membrane that lines the wall of the channel, called the *annulus*, that connects the two cells. The diameter of the annulus varies from about 30–60 nm; its length can vary and may be greater than 1 μm. The lipid and protein composition of the specialized plasma membrane lining the annulus differs from that of the rest of the plasma membrane that surrounds the cell. Second, passing though the center of the plasmodesmata's annulus is a narrow tube, called a *desmotubule*, that is an extension of endoplasmic reticulum (ER) from each of the connected cells. Between the desmotubule and the plasmodesmata's specialized plasma membrane is a gap whose size is regulated and varies between 2–10 nm. This gap is called the *cytoplasmic sleeve*, through which molecules diffuse from the cytosol of one cell to that of the other. Filamentous actin runs throughout the length of the cytoplasmic sleeve. The close apposition of the plasma membrane and ER/desmotubule's membrane in plasmodesmata is an example of a specialized membrane contact site (MCS), such as that described for mitochondria and ER in Chapter 12. A set of transmembrane proteins in the desmotubule called *MCTPs* can span the gap of the cytoplasmic sleeve and bind to anionic phospholipids on the plasma membrane, thus tethering these two membranes. The

MCTP proteins appear to compose spoke-like projections observed by electron microscopy that tether the two membranes (see Figure 20-44c), help determine the size and properties of the cytoplasmic sleeve, and thus control the movement of molecules through plasmodesmata. In animal cells, tunneling nanotubes resemble plasmodesmata in that they are membrane-lined channels that permit molecules to flow between cells (see Section 20.2). However, unlike plasmodesmata, there is no evidence for ER passing through tunneling nanotubes.

There are simple plasmodesmata (with a single pore, like those in Figure 20-44) and complex plasmodesmata that branch into multiple channels. The density of plasmodesmata varies depending on the plant and cell type, and even the smallest meristematic cells have more than a thousand connections with their neighbors. Proteomic analysis suggests that there are more than 115 different proteins that are concentrated in plasmodesmata and play important roles in determining their structures and functions. These include the MCTPs, actin-binding proteins (e.g., formin and the adaptor protein NET1A), a variety of receptor-like proteins (e.g., kinases), and enzymes.

Many types of molecules travel from cell to cell through plasmodesmata. Molecules smaller than about 1000 Da, including a variety of metabolic and signaling compounds (ions, sugars, amino acids), can generally diffuse freely through the cytoplasmic sleeve, whose size and properties are highly regulated. In some

circumstances, the channel is clamped shut; in others, it is dilated sufficiently to permit the passage of molecules larger than 10,000 Da, including some transcription factors, nucleic acid/protein complexes, metabolic products, and even plant viruses. Some of these require special chaperones to facilitate transport. Soluble molecules pass through the cytosolic sleeve, whereas membrane-bound molecules or certain proteins within the ER lumen may pass from cell to cell via the desmotubule. The deposition and breakdown of a glucose polymer called *callose* in the extracellular spaces adjacent to the entrances of the channels (see Figure 20-44a) is thought to regulate the closing and opening of the channels, respectively. Specialized kinases may also phosphorylate plasmodesmal components to regulate their activities (e.g., opening of the channels). Among the factors that affect the permeability of plasmodesmata is the cytosolic Ca^{2+} concentration: an increase in cytosolic Ca^{2+} reversibly inhibits movement of molecules through these structures.

The Molecules That Plants Depend on for Adhesion and Mechanotransduction Differ from Those in Animals

As noted earlier in this section, there are dramatic differences in the organization of cells into tissues in plants and animals. These

differences have determined the distinctive molecular mechanisms by which plant cells are incorporated into tissues and communicate with one another, including their cell-cell and cell-matrix interactions.

Plant Adhesion Molecules

Systematic analyses of the *Arabidopsis* genome and biochemical analyses of other plant species have provided no evidence for the existence of plant homologs of most animal CAMs, adhesion receptors, and ECM components; plants use other adhesive molecules for their cell-cell and cell-matrix interactions. Currently, our understanding of cell-matrix adhesion in plants is less advanced than our understanding of cell-matrix adhesion in animals.

Because plant cells are surrounded by thick cell walls, their assembly into tissues is primarily determined by cell-matrix interactions. Most of the polysaccharides in the cell wall (cellulose, hemicellulose, pectins, glycoproteins) can cross-link to one another. The adhesive properties of pectins are thought to be especially important for determining both the physical characteristics of cell walls and the interactions of the walls with the plasma membranes of the underlying cells. Disruption of the gene encoding glucuronyltransferase 1, a key enzyme in pectin biosynthesis, dramatically interferes with the synthesis of specialized pectins that help hold the cells in meristems tightly together. As a consequence,

the mutation prevents normal cell adhesion and differentiation into photosynthetic cells. In vitro binding assays, combined with in vivo studies and analyses of plant mutants, have identified other macromolecules in the ECM that are important for specialized types of adhesion. For example, a cysteine-rich protein called *stigma/stylar cysteine-rich adhesin (SCA)* and a specialized pectin that binds to SCA mediate normal adhesion of pollen, which contains sperm cells, to the stigma or style in the female reproductive organ of the Easter lily.

A number of plasma membrane proteins exhibit the potential to bind to cell wall polysaccharides, particularly pectins, and thus mediate cell-matrix adhesion. These include receptor-like proteins, such as Wall-Associated Kinases (WAKs), GPI-anchored proteins, Hydroxyproline-Rich Glycoproteins (HRGPs), and Glycosyl Inositol Phosphoceramides (GIPCs). For example, five WAKs and WAK-like proteins are expressed in the plasma membrane of *Arabidopsis* cells. These transmembrane proteins have a cytoplasmic serine/threonine kinase domain, and their extracellular regions contain multiple epidermal growth factor (EGF) repeats, frequently found in animal cell-surface receptors. Some WAKs have an extracellular pectin-binding domain that can recognize and bind full-length pectin and pectin degradation fragments. Such binding has been proposed to help cells monitor and respond to the status of the cell wall during normal growth and in the context of cell-wall damage (wounding) or infection by pathogens. Thus some WAKS in plant cells appear to be

analogous to adhesion receptors in animal cells, binding and sensing the ECM and mediating outside-in signaling.

Mechanosensation in Plants

As with animal cells, plant cells are subject to a variety of mechanical forces (stresses and strains), both internal (e.g., turgor pressure, cytoskeletal forces) and external (e.g., wind), which they sense (mechanosensing) and to which they respond (e.g., alterations in cytoskeletal organization, calcium flux, gene expression, wood formation, cell wall stiffness, and extent and direction of growth). Possible mechanosensors in the cell wall include components whose structures respond to changes in mechanical forces and thus change the properties of the wall and its interactions with the plasma membrane. Potential mechanosensors in the cell's plasma membrane are those components that bind to the cell wall (e.g., receptor-like kinases such as pectin-binding WAKs) and mechanosensitive ion channels. There is evidence that suggests inside-out and outside-in communication via adhesive molecules contribute to plant responses to mechanical forces.

One well-known example of macroscopic plant mechanosensation is the Venus flytrap (*Dionaea muscipula*), first described by the colonial governor of North Carolina, Arthur Dobbs, in 1759. Charles Darwin studied the Venus flytrap extensively, writing a book in 1875 in which he called the plant "one of the most

wonderful in the world" and once noting that he cared more for one of them "than the origin of all the species in the world." The Venus flytrap detects the presence of an insect on its leaf when an insect hits one of its sensory hairs, which are around 200 μm in diameter at the base and 2 mm long. The sensory hair is a multicellular organ that, when bent by prey, puts shear stress on a cluster of cells at its base, which opens mechanosensitive calcium channels. Calcium entry triggers an action potential in the leaf (see Chapter 23) that leads to closing the trap and hormonally induced secretion of digestive enzymes that disassemble the prey into basic nutrients over a one-to-two-week period. ■

We are all familiar with one aspect of cell-wall–mediated adhesion in plants: the softening of fruits, such as tomatoes and strawberries, during ripening. The ripening of fruits is a complex process that influences color, aroma, flavor, nutrient content, and texture (including softening and water content). Ripening of seed-bearing fruit is advantageous because it encourages fruit-eating animals to eat and disperse the seeds or breaks down the uneaten fruit's structure (softening and decay) to release the seeds in situ. However, excessive softening can interfere with successful storage and transport and can reduce shelf life. Expression of a group of cell-wall–degrading enzymes, including pectate lyase (PL), and their remodeling of cell walls by degrading pectin plays a key role in determining the rate and extent of softening. Experiments using both strawberries and tomatoes have suggested that inhibiting the

expression of pectate lyase using either CRISPR gene editing or RNA interference (see Chapter 6) can substantially delay strawberry and tomato softening and may not block other desirable consequences of ripening (changes in color, flavor, etc.). In the future, targeted genetic modifications of cell-wall metabolism may improve the quality of available fruits while reducing the costs of production and distribution. ■

KEY CONCEPTS OF SECTION 20.6

Plant Tissues

- The organization of cells into tissues in plants is fundamentally different from the assembly of animal tissues, primarily because each plant cell is surrounded by a relatively rigid cell wall.
- The plant cell wall comprises layers of cellulose microfibrils embedded within a matrix of hemicellulose, pectin, extensin, and other less abundant molecules.
- Cellulose, a large, linear glucose polymer, assembles spontaneously into microfibrils stabilized by hydrogen bonding.
- The cell wall defines the shapes of plant cells and restricts their elongation. Auxin-induced loosening of the cell wall permits cell elongation.
- Adjacent plant cells can communicate through plasmodesmata, junctions formed by tubes of specialized plasma membrane and ER that connect the cytosols of adjacent cells, and by allowing molecules to pass between cells (see Figure 20-44).
- Plants do not produce homologs of the common adhesion molecules found in animals.
- The molecules mediating cell-matrix adhesion in plants are not as well-defined as those in animals, although both cell wall and plasma membrane molecules implicated in plant cell adhesion have been identified and are under investigation.
- As in the case of animal cells, mechanotransduction in plants plays an important role in maintaining tissue integrity and directing differentiation and development.

trans (intercellular) interactions
transcellular pathway

Review the Concepts

1. Describe the two phenomena that give rise to the diversity of adhesion molecules, such as cadherins. What additional phenomenon gives rise to the diversity of integrins?

2. Cadherins are known to mediate homophilic interactions between cells. What is a homophilic interaction, and how can it be demonstrated experimentally for E-cadherins? What component of the extracellular environment is required for the homophilic interactions mediated by cadherins, and how can this requirement be demonstrated?
3. Together with their role in connecting the lateral membranes of adjacent epithelial cells, adherens junctions play a role in controlling cell shape. What associated intracellular structure and proteins are involved in this role?
4. What is the normal function of tight junctions? What can happen to tissues when tight junctions do not function properly?
5. Gap junctions between cardiac muscle cells and gap junctions between uterine smooth-muscle cells form connections that provide for rapid communication. What is this phenomenon called? How is communication among uterine smooth-muscle cells up-regulated for parturition (childbirth)?
6. What is collagen, and how is it synthesized? How do we know that collagen is required for tissue integrity?
7. Explain how changes in integrin structure mediate outside-in and inside-out signaling.
8. Compare the functions and properties of each of three types of macromolecules that are abundant in the ECM of all tissues.

9. Many proteoglycans have signaling roles. Regulation of feeding behavior by syndecans in the hypothalamic region of the brain is one example. How is this regulation accomplished?
10. You have synthesized an oligopeptide containing an RGD motif surrounded by other amino acids. What is the effect of this peptide when added to a fibroblast cell culture grown on a layer of fibronectin adsorbed to the tissue culture dish? Why does this happen?
11. Describe the major activity and possible localization of the three major subgroups of proteins that remodel or degrade the ECM in physiological or pathological tissue remodeling. Identify a pathological condition in which these proteins play a key role.
12. Blood clotting is a crucial function for mammalian survival. How do the multi-adhesive properties of fibronectin lead to the recruitment of platelets to blood clots?
13. How do changes in molecular connections between the ECM and the cytoskeleton give rise to Duchenne muscular dystrophy?
14. To fight infection, leukocytes move rapidly from the blood into sites of infection in the tissues. What is this process called? How are adhesion molecules involved in this process?
15. The structure of a plant cell wall needs to loosen to accommodate cell growth. What signaling molecule controls this process?

16. Compare plasmodesmata in plant cells with gap junctions and tunneling nanotubes in animal cells.

CHAPTER 21

Responding to the Cellular Environment

Yulia Malega/Shutterstock.

Rapamycin (in black), a clinically important antifungal drug and inhibitor of the mTORC kinase complex, was isolated from the bacterium *Streptomyces hygroscopicus* found on Easter Island. It was named after the native name of the island, Rapa Nui.

OUTLINE

21.1 Regulating Blood Glucose Level
21.2 Integrating Cell Growth Signals with Nutrient and Energy Levels

21.3 Responding to Changes in the Levels of Cholesterol and Unsaturated Fatty Acids
21.4 Responding to Low Oxygen
21.5 Responding to Elevated Temperatures
21.6 Sensing Day and Night: Circadian Rhythms
21.7 Sensing and Responding to the Physical Environment

All cells sense and respond to changes in their environment, often by changing their pattern of gene expression. Bacteria constantly monitor the levels of sugars and amino acids in their environment and respond by swimming toward sources of these nutrients and inducing or repressing genes that enable them to most efficiently metabolize these molecules. Yeasts and other unicellular, eukaryotic organisms also sense the presence of sugars, amino acids, and many other metabolites in their environment and adjust their biosynthetic pathways, membrane transporters, and metabolism accordingly. In Chapter 1, we saw how the green unicellular alga *Chlamydomonas reinhardtii* senses light and swims toward or away from the light source depending on its intensity.

This chapter focuses on the multiple ways cells in metazoans, and particularly vertebrates, sense the levels of glucose, amino acids, lipids such as cholesterol, oxygen, and other chemicals in their environment, as well as day and night and contact with other cells, and respond appropriately. These extracellular signals can have short-term effects that usually occur within minutes and are induced by modification of existing enzymes or other proteins, as we learned in Chapters 3 and 15. All of the extracellular signals we

discuss also affect gene expression and thus induce long-term changes in cell function.

The pathways we describe have much in common with the signaling pathways described in Chapters 8, 15, and 16. **Sensors**, like receptors for extracellular signaling molecules, generally bind a specific target molecule and then undergo a conformational change; **mechanoreceptors** sense changes in the physical environment (e.g., pressure or tension, see Chapter 20). These sensors activate **signal transduction pathways** that can have one or many steps. Ultimately one or more **effector proteins** become activated that induces the cell's response, which can be a short-term change in a metabolic pathway, or induction or repression of specific genes, or both. **Signal amplification** and **feedback repression** (see Chapter 15) characterize all of the signal transduction pathways we describe in this chapter, enabling an appropriate but not overreactive adjustment of the cell's metabolism and pattern of gene expression. These pathways enable a cell to respond to a variety of stresses, for instance, lack of a nutrient or an elevated temperature, and enable **homeostasis**, the restoration of the cell's normal chemical and physical conditions and even the survival of the cell itself.

The availability of blood glucose is regulated during periods of abundance (following a meal) or scarcity (fasting) principally by two hormones, insulin and glucagon. As we learn in Section 21.1, when blood glucose concentrations rise too high, β islet cells in the pancreas, cells that synthesize and store insulin, secrete insulin into

the bloodstream. (The 1923 Nobel Prize in Physiology or Medicine was awarded for the discovery of insulin.) Insulin signals fat and muscle cells to increase their uptake of glucose from the blood; it also signals liver cells to store glucose as glycogen, lowering the glucose concentration in the blood. When blood glucose concentration falls too low, other cells in the islets, α cells, release glucagon from secretory vesicles; glucagon instructs liver cells to release glucose into the blood (see Chapter 15). Working together, insulin and glucagon maintain blood glucose homeostasis, restoring the normal glucose levels of about 5 mM in humans. Defects in these pathways lead to major diseases, including diabetes and cardiovascular disease, with dire consequences for the individual and increasingly for public health.

Cell proliferation, the doubling of cell numbers, requires the presence of one or more growth factors, as discussed in Chapter 16. Cell division also requires the presence of sufficient ATP, amino acids, and other nutrients to produce all of the proteins, nucleic acids, membranes, and other components required to double the cell mass in preparation for division. In Section 21.2 we discuss the **mTOR protein kinase**, a component of a large multiprotein complex called **mTORC1**. mTORC1 contains multiple sensor proteins that detect the levels of specific nutrients, energy availability (ATP levels), and the activity of intracellular signal transduction proteins activated downstream of growth factor receptors. mTOR kinase becomes activated and consequently stimulates cell growth, metabolism, and proliferation only when all of these signals are

present simultaneously; we will see how multiple sensors in the mTORC1 complex interact to activate the mTOR kinase.

Among the many nutrients essential for cell growth and function are membrane lipids and their biosynthetic precursors, including cholesterol and unsaturated fatty acids (see Chapters 2 and 10). Cells obtain the necessary lipids either by biosynthesis or import from the extracellular environment. If there are not enough of these lipids, the cells cannot grow, divide, or function properly. If there is too much, the excess can interfere with normal cell function. In Section 21.3, we learn how cells sense levels of intracellular cholesterol and unsaturated fatty acids and how they respond by adjusting the rates of fatty acid and cholesterol biosynthesis and import so that the cholesterol:phospholipid ratio is kept within the narrow, desirable range required for normal membrane functions. Accumulation of excess cholesterol in our arteries is a major cause of cardiovascular diseases and strokes, and in Chapter 10 we learned how the anti-atherosclerosis medications called *statins* inhibit cholesterol biosynthesis and reduce the concentration of low-density lipoproteins (often called "bad cholesterol"; see Chapter 14) and reduce the formation of atherosclerotic plaques. The 1985 Nobel Prize in Physiology or Medicine was awarded for discoveries of how cholesterol metabolism is regulated.

The Nobel Prize in Physiology or Medicine was awarded in 2019 to three physician scientists for elucidating how metazoan cells sense

and adapt to oxygen availability. In Section 21.4, we learn how a reduction in oxygen levels in blood is sensed by many cells in the body and how the transcription factor Hif-1α coordinates many body responses to low oxygen. At ambient oxygen levels, Hif-1α undergoes covalent modifications by oxygen-requiring enzymes that trigger its polyubiquitination and destruction by proteasomes. Hif-1α becomes progressively more stable as oxygen levels decrease. In certain kidney cells, Hif-1α induces the expression of the erythropoietin gene; erythropoietin in turn increases the production of red blood cells that transport oxygen from the lungs to body tissues (see Chapter 16). In other cells, Hif-1α induces expression of genes to promote survival in low-oxygen conditions. Hif-1α is found only in metazoan animals; we also discuss a different family of oxygen-sensing transcription factors that are expressed both in plants and animals and that arose very early in evolution.

All organisms, be they unicellular, plants, invertebrates, or cold-blooded vertebrates, are subject to changes in the temperatures of their internal and external environments. Even vertebrates feel the effects of elevated temperature during fevers or during the hottest periods of summer days. One of the effects of elevated temperatures is partial unfolding or complete denaturation of many cellular proteins that, if uncorrected, could have lethal consequences for the cell. We learn in Section 21.5 how all studied eukaryotes sense the presence of unfolded proteins by the binding of chaperones to unfolded protein domains (see Chapter 3) and how this leads to the **heat-shock response**, during which a particular transcription factor

becomes activated and then induces the synthesis of many chaperones that enable the cell to survive an elevated temperature until the temperature is reduced to normal. Similar chaperones play key roles in facilitating folding of proteins within the endoplasmic reticulum lumen and mitochondria, as discussed in Chapter 13.

Most living things on Earth are subject to a day-night cycle of almost exactly 24 hours. Their cells contain a **circadian clock**, or **circadian oscillator** — a group of proteins whose signaling oscillates with an endogenous period of 24 hours and that receives daily signals from the environment, primarily daylight and darkness, that keep it on time. These synchronized cell clocks, which we discuss in Section 21.6, make it possible for the organism to anticipate the environmental changes that derive from the day-night cycle and adjust its biology and behavior accordingly. In 2017, the Nobel Prize in Physiology or Medicine was awarded to three scientists for their discoveries of molecular mechanisms controlling the circadian rhythm in fruit flies; similar clocks are found in plant, fungal, and vertebrate cells that adjust many aspects of their function to a day-night cycle. Circadian rhythms in certain brain neurons control aspects of organismal behavior, such that mice and lions are active at night while humans are more active during the day.

During development, cells proliferate and differentiate to generate organs of specific sizes. Indeed, certain mutations in the fly *Drosophila melanogaster* (see Chapter 1) result in excessive organ

growth; one was called *Hippo*, as mutations caused massive overgrowth of larvae that looked like a hippopotamus. When part of an adult liver is surgically removed, the liver rapidly regenerates to its former size; clearly gene products must exist that negatively regulate growth when the appropriate organ size is achieved. In Section 21.7, we discuss the **Hippo pathway**, a protein kinase signaling cascade conserved in all metazoans that senses and integrates multiple environmental cues and modulates cell growth in response to the physical environment. This pathway senses physical and mechanical cues from the extracellular matrix in which the cell is imbedded, senses tension (mechanotransduction), and receives signals from the adherens junctions (Chapter 20) that connect them with other cells. The Hippo pathway regulates the expression of multiple genes involved in growth control and differentiation, and we will see that abnormalities in components of this pathway contribute to developmental disorders, cell transformation, and metastases by many types of cancers.

21.1 Regulating Blood Glucose Level

In this section, we consider how multiple hormones and signal transduction pathways interact, focusing on one of the most important physiological control systems: regulation of the body's need for glucose. Defects in these pathways lead to major diseases, particularly type 2 or *adult-onset* diabetes, a principal cause of blindness, kidney failure, and limb amputations in adults. Cellular responses to changes in amino acids and other nutrients, which are largely reflected in alterations in gene expression, are covered in Section 21.2.

Insulin and Glucagon Work Together to Maintain a Stable Blood Glucose Level

Our focus in this section is mainly on vertebrates, whose normal blood glucose concentration is about 5 mM. Because most body cells, including brain neurons, utilize glucose as their primary energy source, a prolonged fall in blood glucose, called *hypoglycemia*, can cause seizures, loss of consciousness, and death. In contrast, prolonged elevations in blood glucose above 9–10 mM can cause diabetes. During normal daily living, the maintenance of normal blood glucose concentrations depends on the balance between two peptide hormones, **insulin** and **glucagon**, which are

made in distinct and adjacent endocrine cells in island-like domains of the pancreas termed *pancreatic islet cells* (Figure 21-1a) and are stored in secretory vesicles prior to regulated secretion (see Figure 14-2). Insulin, which lowers blood glucose, contains two polypeptide chains linked by disulfide bonds and is synthesized by the β cells in the islets (see Figure 14-24). Glucagon is produced by the α cells in the islets and acts to raise blood glucose by inducing cleavage of glycogen into glucose in the liver and secretion of the glucose into the blood (see Chapter 15). The availability of blood glucose is regulated during periods of abundance (following a meal) or scarcity (following fasting) by the amounts of insulin and glucagon secreted from pancreatic islet β and α cells.

FIGURE 21-1 Secretion of insulin by pancreatic islet β cells in response to a rise in blood glucose above 5 mM. (a) A section of an islet in a human pancreas. Islets comprise about 2 percent of the mass of a pancreas. A human pancreas contains about one million islets, each of which contains about 1000 β cells. β cells, which comprise ~70 percent of islet cells, are revealed by a red histochemical stain for insulin. Glucagon, synthesized in the α cells largely on the periphery of the islet, is visualized by a green stain. The DAPI dye, blue, stains all nuclei. (b) Regulation of insulin secretion. Entry of glucose into pancreatic β cells is mediated by the GLUT2 glucose transporter (step 1). Because the K_m of GLUT2 for glucose

is 20 mM, a rise in extracellular glucose from 5 mM, characteristic of the fasting state, causes a proportional increase in the rate of glucose entry (see Figure 11-5). The conversion of glucose into pyruvate (Figure 12-3) is thus accelerated, resulting in an increase in the concentration of ATP in the cytosol (step 2). The binding of ATP to ATP-sensitive K^+ channels in the β cells closes those channels (step 3), thus reducing the efflux of K^+ ions from the cell. The resulting small depolarization of the plasma membrane from ~ −70 mV to ~ −40 mV (step 4) triggers the opening of voltage-sensitive Ca^{2+} channels (step 5). The influx of Ca^{2+} ions raises the cytosolic Ca^{2+} concentration, triggering the fusion of insulin-containing secretory vesicles with the plasma membrane and the secretion of insulin (step 6). See J. C. Henquin, 2000, *Diabetes* **49**:1751.

Secretion of glucagon from pancreatic α cells is inhibited by insulin when blood glucose is high; secretion is enhanced by signals from the central nervous system when blood glucose should increase. Like the epinephrine receptor, the glucagon receptor, found primarily on liver cells, is coupled to the $G_\alpha s$ protein, whose effector protein is adenylyl cyclase. The binding of glucagon to its receptor induces a rise in cAMP, leading to activation of protein kinase A, which inhibits glycogen synthesis and promotes glycogenolysis, yielding glucose 1-phosphate (see Figure 15-22). Liver cells convert glucose 1-phosphate into glucose, which is released into the blood, thus raising blood glucose back toward its normal fasting level.

Our focus here will be on the hormone insulin, which acts in several short-term and long-term ways to reduce the level of blood glucose:

- Within seconds of its secretion, insulin induces an increase in the uptake of glucose from the blood into muscle and fat cells,

primarily by increasing the number of glucose transporters in the plasma membrane.

- Within seconds to minutes, insulin acts on the liver to both stimulate glycogen synthesis from glucose and accelerate glucose flux through the glycolytic pathway; both processes provide a *sink* that helps lower glucose levels in the blood.
- Insulin released from β cells acts on the nearby α cells in the pancreatic islets to inhibit glucagon synthesis.
- Over a longer time frame of hours, insulin acts on the liver to inhibit synthesis of enzymes that catalyze the process termed **gluconeogenesis** — the synthesis of glucose from smaller metabolites.

In the following sections, we see how insulin secretion is stimulated by a rise in blood glucose and then the multiple ways insulin acts to lower blood glucose.

A Rise in Blood Glucose Triggers Insulin Secretion from the β Islet Cells

After a meal, when blood glucose rises above its normal level of 5 mM, the pancreatic β cells respond to the rise in glucose (and a concurrent rise in amino acids in the blood) by releasing insulin into the blood (Figure 21-1b). We saw in Chapter 14 that these cells store insulin in a dehydrated, almost crystalline form in secretory vesicles; as with all regulated secretory pathways, fusion of these

vesicles with the plasma membrane and secretion of their contents is triggered by a rise in cytosolic Ca^{2+}. Insulin secretion is triggered by a rise in extracellular glucose, which, via GLUT2 glucose transporters (Figure 11-5), causes a proportionate increase in the rate of glucose entry into the cells and a corresponding increase in the rate of glycolysis. The resulting rise in the ratio of cytosolic ATP:ADP concentrations causes closing of an ion channel unique to the β cells, an ATP-gated K^+ channel, reducing the efflux of K^+ ions from the cell. As occurs at the axon termini of nerve cells (see Chapter 23), the resulting depolarization of the plasma membrane from ~ −70 mV to ~ −40 mV triggers the opening of voltage-sensitive Ca^{2+} channels, an increase in cytosolic Ca^{2+}, and insulin secretion.

In Fat and Muscle Cells, Insulin Triggers Fusion of Intracellular Vesicles Containing the GLUT4 Glucose Transporter with the Plasma Membrane, Thus Increasing the Rate of Glucose Uptake

Once secreted from pancreatic β cells, insulin circulates in the blood and binds to insulin receptors, which are present on many different kinds of cells, including liver, muscle and adipocyte (fat) cells. In fat and muscle cells the insulin receptor, a receptor tyrosine kinase (see

Chapter 16), activates several signal transduction pathways leading, within minutes, to a ~10-fold increase in the rate of uptake of glucose from the blood. Once imported, glucose is rapidly phosphorylated by hexokinase to form glucose 6-phosphate (Figure 12-3), which cannot be transported out of the cell; the increase in glucose import therefore results in rapid lowering of the level of blood glucose.

Like the plasma membranes of most body cells, the membranes of fat and muscle cells contain the GLUT1 glucose transporter, which allows the cell to import sufficient glucose for its basal metabolic needs. Fat and muscle cells also express large amounts of a glucose transporter, the insulin-responsive glucose transporter GLUT4, made only by these cells. In resting (unstimulated) cells, virtually all of the GLUT4 is located in small vesicles in the cytosol (Figure 21-2a). While some GLUT4 is in endosomes, most is in a small organelle unique to fat and muscle cells termed the **GLUT4 storage vesicle** (**GSV**; Figure 21-2b). These vesicles, which are separate from but, as we will see, derived from endosomes, are tethered to the Golgi matrix, a network of coiled-coil proteins surrounding the Golgi complex, by a protein termed *TUG* (*T*ether containing a *U*BX domain for *G*LUT4). The N-terminal domain of TUG binds GLUT4 and other vesicle proteins while its C-terminal domain binds Golgi matrix proteins, preventing the movement of GSVs to the plasma membrane in the absence of insulin signaling.

(a) Total GLUT4

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Co

EXPERIMENTAL FIGURE 21-2 Insulin stimulation of fat cells induces translocation of GLUT4 from intracellular vesicles to the plasma membrane. (a) Cultured adipose cells were engineered to express a chimeric protein comprising GLUT4 with a green fluorescent protein (GFP) fused to its C-terminus; live cells were visualized with a confocal fluorescence microscope. In the absence of insulin, virtually all of the GLUT4 is in intracellular membranes that are not connected to the plasma membrane; there is little surface staining. Treatment with insulin triggers fusion of the GLUT4-containing membranes with the plasma membrane, thereby moving GLUT4 to the cell surface and enabling it to transport glucose from the blood into the cell. Arrows highlight GLUT4 present at the plasma membrane; *N* indicates the position of the nucleus. (b) In fat and muscle cells, insulin signaling acts at multiple steps to increase the level of GLUT4 at the plasma membrane. In resting cells, the majority of the GLUT4 protein is localized to specialized GLUT4 storage vesicles (GSVs); much of the GLUT4 is tethered to proteins surrounding the Golgi complex, termed *Golgi matrix proteins*, by the TUG protein and is thus unable to move to the cell surface. Binding of insulin to the insulin receptor leads to activation of a protease (step **1**) that cleaves the TUG protein, releasing GLUT4-containing vesicles from the Golgi matrix (step **2**). The N-terminal fragment of TUG remains bound to the GSVs and binds to the microtubule motor protein kinesin (step **6a**; see Chapter 18), enabling the GSVs to move along microtubules to the cell surface (step **6b**; *below*). Insulin also activates PKB (step **3**; see Figure 16-17). PKB then phosphorylates the Rab GAP protein AS160 (step **4**), inhibiting its ability to accelerate GTP hydrolysis by the GTP-binding protein Rab10 that is attached to a GSV by a covalently attached lipid. Rab10 then accumulates in its active GTP-bound state (step **5**) and directs the GLUT4 storage vesicles to move along microtubules and interact with target proteins on the cell surface (steps **6a** and **6b**). Finally, these GSVs fuse with the plasma membrane (step **7**). This step is catalyzed by another monomeric GTP-binding protein, RalA, when in its active GTP-bound state. PKB stimulates this membrane fusion event by phosphorylating and thus inactivating the RalA GAP protein (step **8**), allowing RalA to bind GTP (step **9**). The resultant increase in plasma membrane GLUT4 allows the cell to incorporate glucose from the extracellular fluids at a rate of about 10 times that of unstimulated cells (step **10**). Following removal of insulin, the plasma membrane GLUT4 is internalized by endocytosis (step **11**) and eventually transported to GSVs (step **12**). Many other proteins, not shown here, participate in these signaling and vesicle budding and fusion events; some of these proteins are also activated downstream of the insulin receptor in pathways other than those requiring PKB. See J. S. Bogan, 2012, *Annu. Rev. Biochem.* **81**:507; A. Klip, T. E. McGraw, and D. E. James, 2019, *J. Biol. Chem.* **294**:11369.

Yu et al., 2007, "The Glucose Transporter 4-Regulating Protein TUG Is Essential for Highly Insulin-Responsive Glucose Uptake in 3T3-L1 Adipocytes," 2007, *J. Biol. Chem.* **282**:7710; permission conveyed through Copyright Clearance Center, Inc.]

Binding of insulin to its receptor triggers activation of a protease that catalyzes a site-specific endoproteolytic cleavage of TUG, separating the N-terminal GLUT4-binding segment from the C-terminus that is anchored to the Golgi matrix. (The signaling pathway by which this takes place is only now being completely identified.) The cleavage of TUG releases GLUT4 storage vesicles from the Golgi matrix and allows the released N-terminal TUG fragment to bind the microtubule motor protein kinesin (see Chapter 18). This initiates the microtubule-based movement of the GSVs to the plasma membrane.

Movement of the GSVs to the plasma membrane is also regulated by two monomeric GTP-binding proteins, RalA and Rab10. Recall that several monomeric GTP-binding proteins are essential for the budding of intracellular transport vesicles (e.g., Sar proteins; see Figures 14-7 and 14-9); others, the Rabs, are essential for vesicle fusion (see Figure 14-11). As with other monomeric GTP-binding proteins, RalA and Rab10 (see Figure 21-2b) switch between the inactive GDP-bound and active GTP-bound state. Rab10 is bound to a GSV by a covalently attached lipid and regulates the movement of GLUT4 vesicles to the plasma membrane; RalA regulates vesicle fusion with the plasma membrane.

Like other receptor tyrosine kinases, the insulin receptor activates the PI-3 kinase/PKB pathway (Figure 16-17). Active PKB, in turn, phosphorylates and by so doing inhibits the GTP → GDP hydrolysis activity of two GAP proteins termed *AS160* and *RGC*; phosphorylation also causes the binding of AS160 to the 14-3-3 protein (Figure 16-13) that sequesters it in the cytosol away from its target Rab proteins. In the basal (unstimulated) state, these GAPs inhibit RalA and Rab10 function by enhancing their rates of GTP hydrolysis, thus keeping the GLUT4 storage vesicles from moving along microtubules to and then fusing with the plasma membrane. Phosphorylation of both GAPs by PKB allows RalA and the Rab10 to accumulate in their active GTP-bound states, enabling them to facilitate multiple steps in the GLUT4 pathway, including transport of the GLUT4 storage vesicles along microtubules to the cell surface and fusion of these vesicles with the plasma membrane (see Figure 21-2b). The mechanisms by which RalA and Rab10 regulate GSV targeting and fusion are the subject of much current research.

As blood glucose level drops, insulin secretion and insulin blood levels drop, and insulin receptors are no longer activated as strongly. In fat and muscle cells, plasma-membrane GLUT4 becomes internalized by endocytosis. When insulin levels are low, GLUT4 diverges from other endocytosed cargo, and moves from endosomes to a segment of the *trans*-Golgi network, and from there to the GSVs where it is stored, thus lowering the level of cell-surface GLUT4 and thus of glucose import.

In the Liver, Insulin Inhibits Glucose Synthesis, Accelerates the Rate of Glycolysis, and Enhances Storage of Glucose as Glycogen

In Chapter 15, we learned that hepatocytes, the major cell type in the liver, are important regulators of glucose metabolism; these cells store excess glucose as glycogen. Insulin acts on the liver in several ways: by inhibiting gluconeogenesis (the metabolic pathway by which metabolites including pyruvate, oxaloacetate, and acetyl CoA are converted to glucose), by accelerating the rate of glycolysis, and by enhancing storage of glucose as glycogen. All of these actions have a common end point — reducing the generation by and release of glucose from hepatocytes and thus reducing the level of glucose in the blood.

Insulin Promotes Glycogen Synthesis from Glucose

Within minutes, insulin stimulation of hepatocytes enhances the conversion of glucose to glycogen; PKB, which is activated downstream of the insulin receptor, plays a crucial role in this process as well. Active PKB phosphorylates GSK3 (the same enzyme that functions in the Wnt and Hh pathways; see Chapter 16). In resting (non-insulin-stimulated) cells, GSK3 is catalytically active

and phosphorylates glycogen synthase, inhibiting its activity and thus blocking glycogen synthesis from glucose (see Figure 15-22). In contrast, in insulin-treated liver, when GSK3 becomes phosphorylated by PKB its catalytic activity is inhibited, so it cannot phosphorylate and thus inhibit glycogen synthase. Insulin-stimulated activation of PKB therefore results in rapid activation of glycogen synthase and glycogen synthesis, helping remove glucose from the circulation and storing it as glycogen in muscle and liver.

Insulin Accelerates the Rate of Glycolysis

As we learned in Chapter 12, phosphofructokinase-1, the enzyme that catalyzes the reaction of fructose 6-phosphate and ATP to form fructose 1,6-bisphosphate and ADP, is a key rate-limiting enzyme in glycolysis. Insulin stimulation results in an enhancement of the activity of phosphofructokinase-1, thus accelerating the catabolism of glucose. It does so in part by enhancing the concentration of fructose 2,6-bisphosphate, as fructose 2,6-bisphosphate allosterically activates phosphofructokinase-1 in liver cells (see Figure 12-4). Through a signal transduction pathway activated downstream of the insulin receptor, the activity of phosphofructokinase-2, the enzyme that forms fructose 2,6-bisphosphate from fructose 6-phosphate and ATP, is enhanced, while the activity of fructose bisphosphate phosphatase-2, the enzyme that hydrolyzes fructose 2,6-bisphosphate back to fructose 6-phosphate and P_i, is inhibited. The end result is enhancement of

phosphofructokinase-1 activity by fructose 2,6-bisphosphate, acceleration of glucose catabolism through the glycolytic pathway, and a reduction in blood glucose levels.

Insulin Inhibits Synthesis of Key Enzymes Essential for Gluconeogenesis

Insulin also acts on hepatocytes to inhibit glucose synthesis from smaller molecules (gluconeogenesis), such as lactate, pyruvate, and acetate (see Chapter 12) and to enhance glycogen synthesis from glucose. Many of these effects are manifest at the level of gene transcription because insulin signaling reduces the expression of genes that encode enzymes that catalyze key steps in gluconeogenesis. The net effect of all these actions is to lower blood glucose to the fasting concentration of about 5 mM while storing the excess glucose intracellularly as glycogen for future use.

If the blood glucose level falls below about 5 mM, for example, due to sudden muscular activity, the reduced insulin secretion from pancreatic β cells results in increased glucagon secretion from the adjacent pancreatic α cells. The secretion of glucagon into the blood quickly triggers the breakdown of glycogen (Figure 15-22) to increase blood glucose levels and thus to restore blood glucose to the normal range.

Unfortunately, these intricate and powerful control systems sometimes fail, causing serious, even life-threatening, diseases, mainly *diabetes mellitus.* In diabetes, the regulation of blood glucose is impaired, leading to persistent elevation of the blood glucose concentration (hyperglycemia) that, if left untreated, leads to the major complications noted above. Type 1 diabetes mellitus, common in children and young adults, is caused by an autoimmune process that destroys the insulin-producing β cells in the pancreas. Sometimes called *insulin-dependent diabetes,* this form of the disease is generally responsive to regulated, lifelong insulin injections and constant external monitoring of blood glucose levels.

Most adults in developed countries with diabetes mellitus have type 2, sometimes called *non-insulin-dependent diabetes*; this condition results from a decrease in the ability of muscle, fat, and liver cells to respond to insulin and from a loss of functional insulin-producing β cells as the body tries to compensate for an elevated glucose level by overproducing insulin. While the underlying causes of this form of the disease are not well understood, obesity is correlated with a huge increase in the incidence of type 2 diabetes. Obesity also contributes to the malfunction of adipocytes, the cells that store fatty acids as triglycerides. The resulting accumulation of lipids (particularly diacylglycerols and sphingolipids) in muscle and liver impairs insulin action in these tissues. Further identification of the signaling pathways that control energy metabolism is expected to

provide insight into the pathophysiology of diabetes, hopefully leading to new methods for its prevention and treatment. ■

KEY CONCEPTS OF SECTION 21.1

Regulating Blood Glucose Level

- The maintenance of normal blood glucose concentrations depends on the balance between two hormones, insulin and glucagon, which are made in adjacent pancreatic islet cells.
- Insulin acts to lower blood glucose when the level rises above the normal 5 mM, while glucagon raises blood glucose levels.
- Insulin secretion by β islet cells is triggered by an increase in glucose influx, which leads to an increase in glycolysis, a rise in ATP levels, a closing of K^+ channels, and an opening of Ca^{2+} channels.
- Insulin acts on fat and muscle cells to increase the rate of glucose import. Activation of insulin receptors triggers several signal transduction pathways that lead to movement of GLUT4 glucose transporters from internal GSVs to and fusion with the plasma membrane.
- Insulin acts on hepatocytes to inhibit glucose synthesis, accelerate the rate of glycolysis, and enhance storage of glucose as glycogen.

21.2 Integrating Cell Growth Signals with Nutrient and Energy Levels

In the previous section, we saw how sensing and maintaining the level of a single molecule, glucose, is essential to the metabolism of vertebrate cells and organisms. However, for some processes cells must be able to sense multiple diverse molecules simultaneously and integrate these signaling inputs into a signal transduction pathway that allows activation of multiple downstream pathways. An important example is the decision of a cell to enter the cell division cycle (see Chapter 19). Initiation of cell division requires not only stimulation by specific growth factors that are on the surface of adjacent cells or in the surrounding medium (see Chapter 16) but also the presence of sufficient amino acids, nucleotides, and other small molecules in the cell's environment. Additionally, the rate of metabolism of glucose, fatty acids, and other energy sources must be sufficient to produce a level of ATP that can power synthesis of all of the proteins, nucleic acids, membranes, and other components necessary for the cell mass to double in preparation for its division.

In this section, we discuss the TOR pathway and its key component, the mTORC1 protein kinase, a large multisubunit complex that regulates cell growth by integrating inputs from multiple cytosolic sensor proteins. We will see in detail how the activity of this kinase

is regulated by levels of certain amino acids in the cytosol and within the lysosome, by the level of ATP, and by the levels of several intracellular signal transduction proteins, mainly kinases, activated downstream of growth-factor receptors. We also learn how the multiple substrates of active mTORC1 kinase in turn activate many signaling pathways necessary for cell growth and proliferation and repress autophagy, which otherwise would recycle these macromolecules back to their small molecule constituents. We also will see how improper activation of the mTORC1 signaling network contributes to human disease and learn that inhibitors of this kinase are used in the clinic.

The TOR pathway was discovered through research into the mechanism of action of rapamycin, an antibiotic produced by a strain of *Streptomyces* bacteria (see the chapter-opening figure). Rapamycin also proved to be useful for suppressing the immune response in organ transplant patients, initially, without knowledge of how it functioned. The *t*arget *o*f *r*apamycin *(TOR)*, a protein that is inhibited by rapamycin, was identified by isolating yeast mutants resistant to rapamycin inhibition of cell growth. Yeast TOR is a large (~2400 amino acid) protein kinase that regulates several cellular processes in yeast cells in response to nutritional status. Both yeast TOR and *m*etazoan *TOR (mTOR)* are incorporated into two multisubunit complexes, mTORC1 and mTORC2. Here we will focus on the better understood mTORC1 complex (Figure 21-3). The large mTORC1 complex is assembled on the cytosolic surface of the

lysosome. We first discuss the multiple signal transduction pathways mTORC1 activates that in turn stimulate cell growth and division, and then the mechanism of mTORC1 activation.

FIGURE 21-3 The mTORC1 complex. (a) Model of the active mTORC1 complex on the surface of the lysosome. The mTORC1 kinase consists of the kinase mTOR, Raptor (regulatory protein associated with mTOR), and many other proteins that regulate mTOR activity. Activation of the mTORC kinase requires its localization to the lysosome surface by the simultaneous conversion of two small GTP-binding proteins, Rheb and RagA, to their active GTP-bound state. Conversion of RagA to its active GTP-bound state occurs when there are sufficient levels of amino acids and other nutrients in the cytosol (Figure 21-4). Conversion of Rheb to its active GTP-bound state occurs downstream of activated kinases such as ERK and PKB that in turn are part of the signal transduction pathways activated downstream of many growth-factor receptors (Figure 21-5); conversion of Rheb to its active GTP-bound state also requires a high level of ATP. Thus mTORC1 integrates signals from many cellular states and in turn regulates many aspects of cell growth and metabolism. Note that both Rheb and the Ragulator protein that binds RagA (and its associated RagC) have lipid-modified terminal residues that tether these components of the supercomplex to the lysosomal membrane. (b) Multiple anabolic signal transduction pathways activated by the mTORC1 complex. Shown are some of the target proteins directly phosphorylated by active mTORC1 that stimulate RNA and protein synthesis and accelerate glycolysis, processes essential for cell growth. See text for details.

[Part (a) data from K. B. Rogala et al., 2019, *Science* **366**(6464):468–475; https://doi.org/10.1126/science.aay0166.]

The Active mTORC1 Complex Activates Many Anabolic Signal Transduction Pathways

In this section, we describe some of the target proteins directly phosphorylated by active mTORC1 that in turn stimulate ribosome, RNA, and protein synthesis, and accelerate the rate of glucose metabolism, all processes essential for cell growth (Figure 21-3b). In the next section, we detail how mTORC1 activity is regulated (Figure 21-3a).

Enhancing the Rate of Messenger RNA Translation and Protein Synthesis

mTORC1 stimulates the rate of messenger RNA translation, and thus overall protein synthesis, through two principal mechanisms: stimulating the production of ribosomes and other molecules necessary for protein synthesis and stimulating the rate of polypeptide chain initiation by ribosomes on mRNAs.

Recall that the first step in translation of a eukaryotic mRNA is binding of the eIF4 initiation complex to the 5′ cap on mRNAs via its eIF4E cap-binding subunit (see Figure 5-36). The concentration of active eIF4E, and thus the rate of polypeptide chain initiation, is down-regulated by a small family of homologous *eIF4E-binding proteins (4E-BPs)* that bind to and in so doing inhibit the interaction

of eIF4E with mRNA 5′ caps. 4E-BPs are directly phosphorylated by active mTORC1. When phosphorylated by mTORC1, 4E-BPs release eIF4E, stimulating the assembly of a translation initiation complex on the mRNA and thus initiation of protein translation. mTORC1 also phosphorylates and activates another protein kinase, S6K, that in turn phosphorylates and thus activates several translation initiation factors, leading to a further increase in the rate of protein synthesis.

Translation of a specific subset of mRNAs that have a string of pyrimidines in their 5′ untranslated regions (called *TOP* mRNAs for *t*ract of *o*ligo*p*yrimidine) is stimulated particularly strongly by phosphorylation of 4E-BP and S6K phosphorylation of another substrate of mTORC1, the RNA binding protein LARP1. TOP mRNAs encode ribosomal proteins and translation initiation and elongation factors; thus enhanced production of these proteins contributes to the production of additional ribosomes in the cell and further enhances the rate of mRNA translation. S6K also phosphorylates its namesake substrate, the S6 subunit of the small ribosomal subunit, but the effects of this phosphorylation on protein synthesis are not understood.

Enhancing the Synthesis of Ribosomal RNAs and tRNAs

Ribosomes constitute about 15 percent of the mass of an average metazoan cell. Active mTORC1 stimulates ribosome production by enhancing the synthesis not only of ribosomal proteins, as noted above, but also of ribosomal RNAs. In ways that are not fully understood, mTORC1 activates the RNA polymerase I transcription factor TIF-1A, stimulating transcription of the large rRNA precursor (see Figure 8-51). mTOR activates transcription by RNA polymerase III as well, by phosphorylating and thereby activating protein kinases that phosphorylate MAF1, a protein inhibitor of RNA polymerase III transcription. MAF1 phosphorylation causes it to be exported from the nucleus, relieving repression of RNA polymerase III transcription and enabling it to synthesize 5S ribosomal RNA as well as many tRNAs. When mTOR activity falls, MAF1 in the cytoplasm is rapidly de-phosphorylated and imported into the nucleus, where it represses transcription by RNA polymerase III.

In addition, mTOR activates two RNA polymerase II activators that stimulate transcription of ribosomal protein and translation factor genes. Finally, mTOR stimulates processing of the rRNA precursor (see Section 9.5) into mature ribosomal RNAs. As a consequence of phosphorylation of these several mTOR substrates, the synthesis and assembly of ribosomes as well as the synthesis of translation factors and tRNAs are greatly increased. Additionally, mTORC1 stimulates the synthesis of pyrimidines, a principal building block of RNA, from smaller molecules, again contributing to the enhanced production of ribosomal and other RNAs. Alternatively, when mTOR kinase activity is inhibited, these substrates become de-

phosphorylated, greatly decreasing the rate of protein synthesis and the production of ribosomes, translation factors, and tRNAs, thus slowing or halting cell growth.

In summary, active mTORC1 stimulates the overall rate of protein synthesis and thus of cell growth by activating transcription factors that enhance expression of ribosomal components, tRNAs, and translation factors. mTORC1 also activates two critical proteins that directly enhance mRNA translation.

Stimulating Glycolysis

Cell growth requires a ready supply of ATP, and activated mTORC1 stimulates glycolysis, the conversion of glucose to pyruvate with the concomitant production of ATP, by increasing expression of the glucose transporter GLUT1, which enhances the rate of glucose import into the cell (see Chapter 11). Activated mTORC1 also increases the production of many enzymes in the glycolytic pathway (see Chapter 12) through increasing the level of the transcription factor hypoxia-inducible factor 1α (HIF-1α). As we will learn in Section 21.4, the HIF-1α protein is rapidly degraded under normal oxygen concentrations but is stabilized during oxygen depletion, a regulation independent of mTORC1 activity. However, because of the selective increase in the rate of translation of HIF-1α mRNA induced by mTORC1, mTORC1 activation leads to an increase in HIF-1α levels even under normal levels of oxygen. HIF-1α in turn increases the rate of transcription of many genes encoding enzymes in the

glycolytic pathway, enhancing ATP levels even in the presence of oxygen.

Inhibiting Autophagy

In addition to enhancing the global rate of cellular protein synthesis and the production of ribosomes, tRNAs, and translation factors, mTORC1 regulates other processes involved in the response to low levels of nutrients, particularly macroautophagy (or simply **autophagy**). During starvation of one or more essential nutrients, when mTOR activity falls, cells degrade cytoplasmic constituents, including whole organelles, to supply energy and precursors for essential cellular processes (see Chapter 14). During this process, a large, double-membrane structure engulfs a region of cytoplasm to form an autophagosome, which then fuses with a lysosome where the entrapped proteins, lipids, and other macromolecules are degraded and their nutrient constituents recycled. Activated mTORC1 inhibits macroautophagy in growing cells when nutrients are plentiful, in part by phosphorylation and inhibition of the autophagy-initiating kinase Unc-51-like kinase-1 (abbreviated *ULK1*). Many of the details of this and other actions of mTORC1 are only now being discovered.

mTORC1 Kinase Activation Requires Amino Acids, a High ATP:AMP Ratio,

and Activation of Signal Transduction Pathways Downstream of Growth-Factor Receptors

Having learned how activated mTORC1 stimulates many aspects of macromolecular synthesis and cell growth, we turn now to its mechanism of activation: how mTORC1 kinase activation simultaneously requires high levels of cytosolic amino acids, a high ATP:AMP ratio, and signals from growth-factor receptors. This process involves the assembly on the cytosolic surface of lysosomes of the huge multisubunit mTORC1 complex depicted in Figure 21-3a.

Activation by Cytosolic Amino Acids

A high level of all 20 amino acids is obviously necessary for protein synthesis to proceed, but somehow vertebrate evolution has selected the levels of only three amino acids, leucine, arginine, and the methionine metabolite *S*-adenosylmethionine (SAM), as the ones that regulate mTORC1 kinase activity (Figure 21-4). (Flies and yeasts utilize different sets of amino acids and nutrients.) The levels of these amino acids in the cytosol regulate a pair of small GTP-binding proteins, RagA and RagC, which are always anchored to a lysosome surface by a lipid attached to Ragulator, a Rag-binding protein.

FIGURE 21-4 Model of the activation of the RagA regulator of the mTORC1 complex by three cytosolic amino acids. RagA and RagC are bound to the Ragulator protein that is tethered to the cytosolic surface of a lysosome membrane by a long covalently attached lipid. Like all small GTP-binding proteins, RagA cycles between an active state with bound GTP and an inactive state with bound GDP. RagA must be in its GTP-bound state (and oddly, RagC in its GDP state) to recruit the core mTORC1 complex to the lysosome surface where it can become activated by other signals downstream of growth-factor receptors. GATOR1 is the GAP that converts active RagA·GTP to inactive RagA·GDP and its activity is regulated by the level of three amino acids, leucine, arginine, and a metabolite of methionine, *S*-adenosylmethionine (SAM). (a) Under conditions of amino acid depletion, GATOR1 is active and promotes the conversion of RagA·GTP to RagA·GDP, thus generating RagA/C heterodimers that cannot bind mTORC1. GATOR2, a protein that binds to and inhibits GATOR1 GAP activity, is constrained from doing so by binding to the unoccupied cytosolic leucine receptor Sestrin and the unoccupied arginine receptor CASTOR. SAMTOR, the cytosolic receptor for SAM, when not bound to SAM binds to and activates GATOR1 activity, further favoring the conversion of RagA·GTP to RagA·GDP. (b) In the presence of sufficient arginine, leucine, and SAM, the GAP activity of GATOR1 becomes inactivated and RagA accumulates in the active GTP-bound state. Under these amino acid–replete conditions, leucine, arginine, and methionine-derived SAM directly bind to their sensors, Sestrin, CASTOR, and SAMTOR, respectively. This triggers inhibition of GATOR1 GAP activity: release of Sestrin and CASTOR from GATOR2 allows GATOR2 to bind to and inhibit GATOR1 through an unknown mechanism, and SAMTOR is unable to activate GATOR1 GAP activity. Efflux of

arginine from the lumen of the lysosome into the cytosol, catalyzed by the transport protein SLC38A9, also contributes to accumulation of RagA in its GTP bound active state. RagA·GTP in turn binds mTOR kinase to the lysosome surface, but activation of mTORC1 kinase activity requires additional signals downstream of growth-factor receptors (Figure 21-5). See A. J. Valvezan and B. D. Manning, 2019, *Nat. Metab.* **1**:321.

The small GTP-binding protein RagA is a key regulator of mTORC1 activity; it enables mTORC1 kinase activity to become activated only when the levels of leucine, arginine, and SAM in the cytosol are sufficiently high. (The associated GTP-binding protein RagC has a minor role in mTORC regulation, and oddly its active state is one with a bound GDP, not GTP.) Like all small GTP-binding proteins, RagA shuttles between its active GTP-bound and inactive GDP bound state; RagA must be in its GTP-bound state to recruit the core mTOR kinase complex to the lysosome surface where it can become activated by other signals downstream of growth-factor receptors. The RagA GEF, the lysosome membrane protein SLC38A9 that also functions as an arginine regulated transport protein for several amino acids, continuously triggers the dissociation of the GDP from RagA·GDP, promoting the binding of GTP to RagA to form RagA·GTP. Rag regulation focuses on GATOR1, the GAP that converts active RagA·GTP to the inactive RagA·GDP.

GATOR1 is active when any of the three crucial amino acids, leucine, arginine, and SAM, are depleted in the cytosol, putting RagA in the GDP state and blocking recruitment of mTOR to the lysosome (Figure 21-4a). Binding of another protein complex, termed *GATOR2*,

to GATOR1 inhibits the GATOR1 GAP activity. However, if the levels of arginine or leucine are low, the binding of GATOR2 to GATOR1 is blocked, probably because GATOR2 becomes bound instead to the unoccupied arginine sensor *CASTOR (c*ellular *a*rginine *s*ensor for m*TOR*C1) or the unoccupied leucine sensor Sestrin2. When present at sufficient levels, arginine and leucine bind to defined sites on CASTOR and Sestrin2, respectively. This binding triggers conformational changes that cause CASTOR and Sestrin2 to dissociate from their inhibitory interactions with GATOR2, allowing GATOR2 to bind to GATOR1 and inhibit GATOR1 GAP activity; this promotes accumulation of RagA in its active GTP-bound state (Figure 21-4b), capable of recruiting mTOR to the complex on the surface of the lysosome.

SAMTOR, the SAM-binding protein, works differently. In the absence of SAM, SAMTOR binds directly to GATOR1 and enhances its GAP activity; binding of SAM to SAMTOR prevents its binding to GATOR1 and reduces GATOR1 GAP activity. Efflux of arginine from the lumen of the lysosome into the cytosol, catalyzed by the transport protein SLC38A9, also contributes to accumulation of RagA in its GTP bound active state.

Thus RagA accumulates in the active GTP-bound state only when there are sufficient levels of leucine, arginine, and SAM in the cytosol. RagA·GTP in turn recruits the inactive mTOR from the cytosol to the lysosome surface, but activation of mTORC1 kinase

activity requires additional signals downstream of growth factor receptors, as we see in the next section.

The mTORC1 Complex Is Activated by a High ATP:AMP Ratio and by ERK and PKB Kinases Activated Downstream of Growth Factor Receptors

Having sufficient levels of amino acids, nucleotides, and other small molecules is necessary for a cell to undergo division, but it is not sufficient. The key to understanding how activation of growth factor receptors also promotes the activation of mTORC1 is another small GTP-binding protein, Rheb (Figure 21-5). Like RagA, Rheb switches between its active GTP-bound and inactive GDP-bound state. Rheb is tethered to the surface of the lysosome by a covalently attached lipid, and it must be in its GTP-bound state to bind to and activate the mTOR complex that has been brought to the lysosome surface by RagA·GTP.

FIGURE 21-5 Model of the activation of the mTORC1 complex by a high ATP:AMP ratio and by kinases activated downstream of growth factor

receptors. The presence of sufficient levels of three amino acids in the cytosol is required to bind the mTOR complex to the lysosome surface (see Figure 21-4). Full activation of mTORC1 kinase activity requires the conversion of the inactive Rheb·GDP protein to its active Rheb·GTP state by kinases activated downstream of growth factor receptors and by a high ATP:AMP ratio. The TSC GAP complex is the only well-established regulator of Rheb identified to date. (a) In absence of growth factors or in a state of low ATP, the mTORC1 kinase is anchored to the lysosome surface (Figure 12-4) but is catalytically inactive because Rheb accumulates in the GDP-bound state and is unable to activate mTORC1 kinase activity. In the absence of growth factor signaling the TSC protein complex, comprising TSC1 and TSC2, localizes to the lysosome surface. TSC possesses highly specific GTPase-activating protein (GAP) activity toward Rheb and thus converts Rheb to the inactive GDP-bound state. A low-energy state, such as during glucose deprivation, results in an increase in the level of cytosolic AMP, which activates the AMP-activated protein kinase AMPK. AMPK phosphorylates TSC2 at a site that further activates the GAP activity of the TSC complex toward Rheb·GTP. Thus a low ATP:AMP ratio also causes Rheb to accumulate in the inactive GDP-bound state and prevents binding and activation of the mTORC1 complex. (b) Addition of growth factors causes Rheb to accumulate in the GTP-bound state, activating mTORC1 kinase activity. TSC2 is a heavily phosphorylated protein, and several protein kinases activated downstream of different growth factor receptors phosphorylate sites on the TSC2 subunit of the TSC complex, inactivating TSC GAP activity and causing dissociation of the TSC complex from lysosomal-bound Rheb. Two such kinases are depicted here, protein kinase B (PKB), activated by the PI-3 kinase pathway (Figure 16-17) and MAP kinase (MAPK), activated by the Ras/MAP kinase pathway (Figure 16-13). Inhibition of TSC GAP activity by these phosphorylation events causes Rheb to accumulate in its active GTP-bound state, able to bind a subunit of the mTORC1 complex already linked to the lysosome membrane, and by so doing activating mTORC1 kinase activity and triggering multiple downstream signal transduction pathways. See A. J. Valvezan and B. D. Manning, 2019, *Nat. Metab.* **1**:321.

As with RagA, GEF proteins, whose identity is unknown, continuously trigger dissociation of the GDP from Rheb·GDP and allow formation of Rheb·GTP and thus activation of mTORC1. Regulation is focused on the GAP that converts the active Rheb·GTP to inactive Rheb·GDP, a heterodimer composed of subunits TSC1 and TSC2, named for their involvement in the medical syndrome *t*uberous *s*clerosis *c*omplex, as discussed below. This TSC complex converts Rheb to its GDP-bound conformation, which does not bind mTOR or activate mTORC1 kinase activity.

TSC2 is phosphorylated by multiple protein kinases that regulate its activity and thus the ability of mTORC1 to accumulate in its active state on the lysosomal surface (Figures 21-5a and b). As we learned in Chapter 16, signaling from many cell-surface growth factor receptor tyrosine kinases leads to activation of the Ras MAPK pathway and MAP kinase (MAPK) in particular. Protein kinase B (PKB) is also activated as part of the PI-3 kinase signaling pathway downstream of many receptor tyrosine kinases. Both MAPK and PKB phosphorylate TSC1/TSC2 at sites that inhibit its GAP activity, causing an increase in accumulation of Rheb·GTP and activation of mTORC1 kinase activity (Figure 21-5b). This type of regulation through cell-surface receptors links the control of cell growth to developmental processes controlled by cell-cell interactions.

Cells also require a high concentration of ATP to undergo proliferation. A reduction in ATP levels cause an increase in ADP

and AMP levels; an accumulation of AMP triggers activation of AMP-activated protein kinase (AMPK). Active AMPK phosphorylates distinct sites on TSC2 that enhance its GAP activity and thus turn off Rheb·GTP–mTORC1 signaling under conditions of cellular energy depletion (Figure 21-5a). AMPK is inactive under conditions of sufficient ATP, but hypoxia and other cellular stresses also activate the TSC1/TSC2 Rheb-GAP.

In summary, activation of MAPK, PKB, and other kinases downstream of growth factor receptors, together with a high cytosolic level of ATP, cause Rheb to accumulate in its active GTP state and to bind to and activate the mTORC1 kinase already at the surface of the lysosome, triggering the multiple downstream anabolic processes discussed above.

Genes encoding components of the mTOR pathway are mutated in many human cancers, resulting in cell growth in the absence of normal growth signals. TSC1 and TSC2 (see Figure 21-5) were initially identified because one or the other of these proteins is mutated in a rare human genetic syndrome: *t*uberous *s*clerosis *c*omplex. Patients with this disorder develop benign tumors in multiple tissues. The disease results because inactivation of either TSC1 or TSC2 eliminates the Rheb-GAP activity of the TSC1/TSC2 heterodimer, resulting in an abnormally high and unregulated level of Rheb·GTP and in the resulting high, unregulated activity of mTORC1. Mutations in components of cell-surface receptor signal

transduction pathways that lead to inhibition of TSC1/TSC2 Rheb-GAP activity are also common in human tumors and contribute to cell growth and replication in the absence of normal signals for growth and proliferation (see Chapter 25).

High mTORC1 protein kinase activity in tumors correlates with a poor clinical prognosis. Consequently, mTOR inhibitors are currently in clinical trials to test their effectiveness for treating cancers in conjunction with other modes of therapy. Rapamycin and other structurally related mTOR inhibitors are potent suppressors of the immune response because they inhibit activation and replication of T lymphocytes in response to foreign antigens (see Chapter 24). Several viruses encode proteins that activate mTOR early after viral infection. The resulting stimulation of translation has an obvious selective advantage for these cellular parasites. ■

KEY CONCEPTS OF SECTION 21.2

Integrating Cell Growth Signals with Nutrient and Energy Levels

- The mTORC1 kinase complex is assembled on the cytosolic surface of the lysosome and consists of the kinase mTOR, the small GTP-binding proteins RagA and Rheb, and many other proteins that regulate mTOR kinase activity (see Figure 21-3).
- The active mTORC1 kinase activates many anabolic signal transduction pathways, including mRNA translation, synthesis of ribosomal RNAs and proteins and tRNAs, and glycolysis, and inhibits autophagy (see Figure 21-3b).
- mTORC1 kinase activation requires the presence in the cytosol of the amino acids arginine, leucine, and *S*-adenosylmethionine. In the absence of any these amino acids GATOR1, the GAP for RagA, causes RagA to accumulate in the GDP-bound state; the

RagA·GDP complex is unable to bring the mTOR kinase to the lysosome surface where it can become activated.

- Binding of these three amino acids to their respective cytosolic sensor proteins triggers an inhibition of the GATOR GAP activity, allowing RagA to accumulate in the active GTP-bound state where it tethers the mTOR kinase to the surface of the lysosome (see Figure 21-4).
- Activation of the mTOR kinase also requires a high ATP:AMP ratio and active ERK and PKB, kinases that are activated downstream of receptor tyrosine kinases. These signaling pathways act on the TSC complex, a GAP for another small GTP-binding protein called *Rheb*, to allow Rheb to accumulate in the active GTP-bound state.
- Accumulation of Rheb·GTP triggers activation of the mTOR kinase that has been tethered to the lysosome surface by RagA·GTP (see Figure 21-5).

21.3 Responding to Changes in the Levels of Cholesterol and Unsaturated Fatty Acids

All cells need to control the amount and composition of membrane lipids. We learned in Chapter 10 that cells must maintain an appropriate fluidity of their membranes and that this is determined by both the amount of cholesterol or other steroids in each cellular membrane and the percentage of unsaturated fatty acids in membrane phospholipids. Indeed, a cell would soon face a crisis if it did not have enough phospholipids to make adequate amounts of membranes or had so much cholesterol that large crystals formed and damaged cellular structures (see Chapter 10). Here we describe how cells maintain cholesterol and fatty acid homeostasis by regulating both the synthesis of enzymes that catalyze key steps in their biosynthesis and the import of exogenous cholesterol from the extracellular fluid. Critical features of this regulation are the sensing of these metabolites by proteins in the endoplasmic reticulum.

Fatty Acid and Cholesterol Biosynthesis as Well as Cholesterol Import Are Regulated at the Level of Gene Transcription

The transcription of genes encoding many enzymes in the cholesterol biosynthetic pathway (see Figure 10-26) is subject to feedback regulation. When cellular cholesterol levels are adequate, cholesterol biosynthesis is suppressed so that excess unesterified cholesterol, which can be toxic, does not accumulate. When cellular cholesterol levels fall too low, threatening the integrity of many cell membranes, biosynthesis is increased. Synthesis of one of the enzymes in the cholesterol biosynthetic pathway, HMG-CoA reductase, is tightly regulated as is the rate-controlling enzyme in cholesterol biosynthesis.

Feedback regulation also controls the import of extracellular cholesterol. As we learned in Chapter 14, lipoproteins are lipid-filled particles that transport hydrophobic molecules through the circulatory system. In humans, the most abundant transporter of cholesterol, in the form of cholesteryl esters, is low-density lipoprotein (LDL; see Figure 14-27). LDL delivers its cholesterol to cells by binding to cell-surface LDL receptors, which mediate the endocytic uptake of LDL particles and their subsequent disassembly in lysosomes, from where the cholesterol enters the cellular pool of cholesterol (see Figure 14-29). The transcription of LDL receptors is transcriptionally regulated to maintain cellular cholesterol homeostasis, and similar systems are used to control unsaturated fatty acid levels.

Sterol Regulatory Elements (SREs)

The levels of sterols such as cholesterol, as well as unsaturated fatty acids, regulate the levels of expression of a number of genes in a cell. The promoters of most cholesterol-sensitive and unsaturated fatty acid–sensitive genes, including HMG-CoA and the LDL receptor, contain one or more 10-base-pair *sterol regulatory elements (SREs)*, or SRE half-sites, in their promoters. (These SREs differ from the *s*erum *r*esponse *e*lements that control many early response genes, discussed in Section 16.2.) The interaction of lipid-regulated transcription factors called **SRE-binding proteins** (**SREBPs**) with these response elements modulates the expression of the target genes.

Mammals express three isoforms of SREBP: SREBP-1a and SREBP-1c, which are generated from alternatively spliced RNAs produced from the same gene; and SREBP-2, which is encoded by a different gene. Together, these transcription factors control expression of proteins that regulate availability not only of cholesterol, but also of fatty acids and the triglycerides and phospholipids made from fatty acids. In mammalian cells, SREBP-1a and SREBP-1c exert a greater influence on fatty acid metabolism than on cholesterol metabolism, whereas the reverse is the case for SREBP-2.

How do cells sense how much cholesterol and unsaturated fatty acids they have, and how are these signals used to control the level of SREBPs in the nucleus and thus gene expression? The SREBP-mediated pathway begins in the membranes of the endoplasmic

reticulum (ER) and includes several other proteins besides SREBP. In Chapter 16, we saw how *regulated intramembrane proteolysis* plays a key role in the Notch and EGF signaling pathways; here we see that *regulated intramembrane proteolysis* also plays an important role in this cellular response to altered cholesterol and fatty acid levels.

The Endoplasmic Reticulum SCAP Protein Senses the Level of Cellular Cholesterol

When cells have adequate levels of cholesterol, SREBP is found in the ER membrane complexed with SCAP (SREBP cleavage-activating protein), insig-1 (or its close homolog insig-2), and perhaps other proteins (Figure 21-6a). SREBP has three distinct domains: an N-terminal cytosolic domain, containing a basic helix-loop-helix (bHLH) DNA-binding motif (see Figure 8-25d), that functions as a transcription factor when cleaved from the rest of SREBP; a central membrane-anchoring domain containing two transmembrane α helices; and a C-terminal cytosolic-facing regulatory domain.

FIGURE 21-6 Cholesterol-sensitive control of SREBP activation. The cellular pool of cholesterol is monitored by the cholesterol-sensor SCAP, located in the ER membrane and stably bound via its C-terminus to the C-terminus of the membrane protein SREBP. Membrane-spanning helices 2–6 of SCAP (orange with black lines) form the sterol-sensing domain. (a) When cholesterol levels are high enough that ER cholesterol exceeds 5 percent of total ER membrane lipid molecules, cholesterol binds to the sterol-sensing domain in SCAP, triggering a conformational change that enables the SREBP/SCAP-cholesterol complex to bind to insig-1(2), anchoring the entire SCAP-SREBP complex in the ER membrane. (b) At low-cholesterol levels, cholesterol dissociates from the SCAP sterol-sensing domain, triggering a reverse conformational change that both dissociates SCAP from insig-1(2) and enables SCAP to bind to Sec24 (green), a subunit of the COPII complex (see Figure 14-9). As a consequence, the SCAP-SREBP complex enters COPII-coated vesicles that transport it to the Golgi. In the Golgi, the sequential cleavage of SREBP by the site 1 and site 2 proteases (S1P, S2P) releases the N-terminal bHLH transcription factor domain of SREBP into the cytosol, which then translocates to the nucleus. There the released bHLH domain of SREBP, called *nuclear SREBP (nSREBP)*, controls the transcription of genes containing sterol regulatory elements (SREs) in their promoters The SCAP protein recycles from the Golgi back to the ER (not shown). See M. S. Brown, A. Radhakrishnan, and J. L. Goldstein, 2018, *Annu. Rev. Biochem.* **87**:783–807; and R. A. DeBose-Boyd and J. Ye, 2018, *Trends Biochem. Sci.* **43**:358–368.

SCAP has eight transmembrane α helices and a large C-terminal cytosolic domain that binds to the regulatory domain of SREBP. Five of the transmembrane α helices in SCAP form a *sterol-sensing domain* similar to that in HMG-CoA reductase (see Figure 21-6a; also see Section 10.3). When cholesterol binds to the sterol-sensing domain in SCAP, SCAP assumes a conformation such that it binds to insig-1(2). When the SCAP-cholesterol complex is tightly bound to insig-1(2), it is in a conformation that blocks its binding to the Sec24 subunit of the COPII vesicle coat complex (see Figure 14-9). This prevents incorporation of the SCAP-SREBP complex into COPII ER-to-Golgi transport vesicles (see Chapter 14). As a consequence the SCAP-SREBP complex is retained in the ER, and thus the transcription factor in SREBP's N-terminal domain cannot enter the nucleus and regulate gene expression. This occurs when cholesterol levels in the ER membrane exceed 5 percent of total ER membrane lipids.

Regulated Intramembrane Proteolysis of SREBP in the Golgi Releases a bHLH Transcription Factor That Acts to Maintain Appropriate Phospholipid and Cholesterol Levels

SCAP releases its bound cholesterol when cholesterol levels in the ER membrane drop to less than 5 percent of ER lipids, a value that reflects normal cellular cholesterol levels. Consequently, Insig-1(2) can no longer bind to the cholesterol-free SCAP, and the SCAP-SREBP complex moves from the ER to the Golgi complex via COPII vesicles (Figure 21-6b). SREBP is then cleaved sequentially at two sites by two proteases that are resident in the Golgi membrane. Site-1 protease (S1P) cleaves SREBP in its luminal loop, separating the protein into two membrane-bound halves. S1P-mediated cleavage renders the N-terminal half of SREBP a substrate for the Site-2 protease (S2P), which releases the N-terminal bHLH-containing domain of SREBP into the cytosol by cleaving the intermediate near the cytosol-membrane boundary, an example of *regulated intramembrane proteolysis*. This protein, also called *nSREBP (nuclear SREBP)*, is rapidly translocated into the nucleus, where it activates transcription of genes containing sterol regulatory elements (SREs) in their promoters.

SREBP-2 primarily activates transcription of genes required for cholesterol synthesis and uptake such as those encoding the LDL receptor and HMG-CoA reductase. Thus a reduction in cellular cholesterol, by activating the *Insig-1(2)/SCAP/SREBP pathway*, triggers expression of genes encoding proteins that both import cholesterol into the cell (the LDL receptor) and synthesize cholesterol from small precursor molecules (HMG-CoA reductase).

SREBP-1a and SREBP-1c preferentially activate transcription of genes required for fatty acid and triglyceride synthesis. The level of unsaturated (but not saturated) fatty acids also regulates cleavage of SREBP-1, but by a slightly different mechanism. In cells deprived of unsaturated fatty acids, Insig-1 becomes a substrate for polyubiquitination, extraction from the ER membrane into the cytosol by the process known as *ERAD (ER-a*ssociated *d*egradation; end of Section 13.3), and subsequent degradation by proteasomes. In the absence of Insig-1, SCAP-1 assumes a conformation enabling it to bind the Sec24 subunit of COPII vesicles, similar to the low-cholesterol situation diagrammed in Figure 21-6b. This initiates transport of SCAP-bound SREBP from the ER to the Golgi, where it undergoes proteolytic cleavage by S1P and S2P that releases its bHLH-containing SREBP-1 transcription factor domain, enabling it to activate expression of genes required for synthesis of fatty acids and triglycerides. In all cases, after cleavage of SREBP in the Golgi, SCAP apparently recycles back to the ER, where it can interact with insig-1(2) and another intact SREBP molecule.

High-level transcription of SRE-controlled genes requires the ongoing generation of new nSREBP because this transcription factor is degraded fairly rapidly by the ubiquitin-mediated proteasomal pathway (see Chapter 3). The rapid generation and degradation of nSREBP also helps cells respond quickly to changes in levels of intracellular cholesterol and fatty acids.

Under some circumstances (e.g., during cell growth), cells need an increased supply of all essential membrane lipids and their fatty acid precursors, processes that require coordinate regulation of many metabolic pathways. In the liver, mTOR, after it becomes activated following stimulation by many growth factor receptors (Section 21.2), directly activates transcription of the *SREB-1c* gene. This in turn results in increased transcription of all of its downstream target genes that encode proteins catalyzing steps in fatty acid synthesis.

KEY CONCEPTS OF SECTION 21.3

Responding to Changes in the Levels of Cholesterol and Unsaturated Fatty Acids

- Vertebrate cells maintain a constant level of cholesterol in their membranes.
- The cellular pool of cholesterol is monitored in the ER membrane by the SCAP protein, which is in a stable complex with full-length SREBP.
- At high-cholesterol levels, cholesterol is bound to the SREBP-SCAP complex, which in turn is bound to the ER protein Insig-1(2), anchoring the entire SREBP-SCAP-cholesterol complex in the ER membrane and preventing its transport to the Golgi and subsequent release of its active nSREBP domain, a transcription factor.
- At low-cholesterol levels, cholesterol dissociates from the SREBP-SCAP complex, triggering conformational changes that lead to the dissociation of SCAP from Insig-1(2), the binding of SREBP and SCAP to the COPII coat, and transport of the SREBP-SCAP complex to the Golgi.
- In the Golgi, cleavage of SREBP by two proteases releases the N-terminal transcription factor, bHLH domain of SREBP (nSREBP), which translocates to the nucleus and activates expression of genes containing sterol regulatory elements (SREs) in their promoters. Among these genes are those that encode proteins that import cholesterol into the cell and enzymes that catalyze key steps in the biosynthesis of cholesterol.
- SREBP-2 primarily regulates cholesterol import and synthesis while SREBP-1a and SREBP-1c primarily regulates unesterified fatty acid synthesis.

21.4 Responding to Low Oxygen

Oxygen is essential for metazoan life, and in Chapter 12 we learned how mitochondria produce ATP from ADP and P_i by oxidizing metabolites derived from glucose, fatty acids, and amino acids. Many organs, such as the brain and heart, cannot use anaerobic glycolysis to produce sufficient ATP and thus are completely dependent on production of ATP through oxidative phosphorylation. In this section, we describe how cells sense drops in the level of oxygen in their environment and respond to this stress, as happens when we ascend to a high altitude or during disease states such as cardiopulmonary failure, where the heart or lungs cannot generate sufficient levels of oxygen-bound hemoglobin in the bloodstream. We will learn how, in metazoans, one transcription factor, Hif-1α coordinates the many cellular responses to low oxygen, how Hif-1α is produced but rapidly degraded by cells under ambient oxygen levels, and how as oxygen levels decrease Hif-1α becomes progressively more stable. Hif-1α activates transcription of hypoxia-induced genes by binding to *h*ypoxia-*r*esponsive *e*lements (HRE) in the promoter or enhancer of oxygen-responsive genes. Hif-1α is found only in metazoan animals, but recent work has uncovered a different family of oxygen-sensing transcription factors that are conserved in both animals and plants. Like Hif-1α these proteins are degraded at ambient oxygen, but by a different mechanism.

Induction of the Erythropoietin Gene at Low Oxygen Levels

Red blood cells transport oxygen from the lungs to all body cells, and maintaining a precise level of red blood cells of about 40–50 percent of blood volume is important for normal body functions. We learned in Chapter 16 (Figure 16-18a) that the cytokine erythropoietin (Epo) is the principal hormone that stimulates red blood cell formation, and that Epo is synthesized by certain cells in the liver and kidney as oxygen levels drop. At one time these cells were thought to be one of the few in the body that respond to low oxygen.

In the early 1990s, the key discovery was made that when liver cells were subjected to low oxygen, a then-novel protein bound to the HRE, with a core sequence 5′-CGTG-3′, in the 3′ enhancer segment of the erythropoietin gene. Characterization of the protein, now called *h*ypoxia-*i*nducible *f*actor 1 alpha or simply **Hif-1α** showed that it was present only in cells cultured in a low-oxygen environment and that Hif-1α bound to HREs as a homodimer with a second protein, called *Hif-1β*, whose level was not regulated by oxygen (Figure 21-7a).

FIGURE 21-7 Degradation of the Hif-1α transcription factor at ambient oxygen levels. (a) Low (0.5 percent) oxygen. Hif-1α is stable and functional. It forms a heterodimer with Hif-1β, binds to HRE elements in the promoters or enhancers of many hypoxia-responsive genes, and induces their transcription. (b) Medium (1–2 percent) oxygen. The asparaginyl hydroxylase FIH is able to bind sufficient oxygen to become catalytically active and transfer an OH group to an asparagine residue on the Hif-1α protein. Hydroxylation blocks the ability of Hif-1α to bind the transcriptional co-activators CBP and p300 and thus activate gene transcription. (c) High (above 4 percent) oxygen. (step 1) The prolyl hydroxylase PHD2 is able to bind sufficient oxygen to become activated and transfer an OH group to two proline residues in Hif-1α protein. (step 2) Each of these hydroxyproline residues form a part of a binding site for the VHL subunit of an E3 ubiquitin ligase. (step 3) The E3 ligase then adds a polyubiquitin chain that triggers immediate degradation of the Hif-1α protein by the proteasome. See text for details.

Oxygen Sensing and Regulated Hif-1α Expression Is a Property of All Nucleated Mammalian Cells

Soon after this discovery, it was shown that the Hif-1α gene is transcribed into mRNA in all body cells regardless of oxygen levels, but that the Hif-1α protein is present only when oxygen levels are very low. As an example, in cultured HeLa cells, the levels of Hif-1α protein and Hif-1α DNA-binding activity increased exponentially as the cellular oxygen concentration decreased, with maximum values at 0.5 percent oxygen and half-maximal values at 1.5 to 2 percent oxygen, compared to ~20 percent oxygen at ambient levels. Indeed, it was soon demonstrated that Hif-1α expression triggered synthesis of *v*ascular *e*ndothelial *g*rowth *f*actor (VEGF), a secreted hormone that stimulates formation of capillaries, tiny blood vessels that connect arteries and veins and increase oxygen delivery to the surrounding tissues. HRE sequences were also found in the enhancers of many genes encoding glycolytic enzymes, and Hif-1α stabilization triggered expression of these genes. In particular, genes encoding several proteins that catalyze regulated and rate-limiting steps in the glycolytic pathway [phosphofructokinase, pyruvate kinase, and lactate dehydrogenase (see Section 12.1)] are strongly induced by Hif-1α at low oxygen levels and promote ATP synthesis in an oxygen-independent manner.

Hif-1α Function and Stability Are Blocked at Ambient Oxygen Levels

Hif-1α protein is synthesized at almost the same rate at low and ambient oxygen levels, but it is rapidly degraded in ambient oxygen. The key to understanding how this happens came with the discovery of a set of proline and asparagine hydroxylation enzymes, iron-containing enzymes that utilize as substrates molecular oxygen and the citric acid cycle intermediate alpha ketoglutarate (see Figure 12-13) and that add a hydroxyl group to the 4-carbon atom of a proline residue or to the 3-carbon atom of an asparagine residue in a protein (as shown below).

Clearly the *p*roline *hyd*roxylase (PHD) enzyme as shown above and the similar asparagine hydroxylase can function only when there is sufficient oxygen in the cell!

There are two checkpoints, both based on oxygen-dependent hydroxylase enzymes, which prevent Hif-1α activity at ambient oxygen. As oxygen levels rise above 0.5 percent, the asparaginyl hydroxylase FIH is the first to become activated (Figure 21-7b). FIH transfers an OH group to a specific asparagine residue in the C-

terminal transactivation domain of the Hif-1α protein; hydroxylation blocks the ability of the Hif-1α protein, bound to an HRE, to bind the transcriptional co-activators CBP and p300 (Chapter 8) and thus blocks the ability of Hif-1α to activate transcription.

At slightly higher oxygen concentrations, the PHD2 enzyme becomes activated and adds a hydroxyl group to two proline residues in the Hif-1α protein (Figure 21-7c). Each of these hydroxyl proline residues on Hif-1α forms a part of a separate binding site for the VHL subunit of a specific E3 ubiquitin ligase. The ligase then adds a polyubiquitin chain to the Hif-1α protein, triggering immediate degradation of Hif-1α by the proteasome. Thus the Hif-1α protein is present in cells only when the oxygen level is very low, and any residual Hif-1α protein remaining at moderate oxygen levels becomes inactive because of asparagine hydroxylation.

Interestingly, Hif-1α is the only known target of the PHD enzyme PHD2, and inactivation of PHD2 in mice causes polycythemia, a production of excess numbers of red blood cells. However, the two other human proline hydroxylase enzymes, PHD1 and PHD3, use molecular oxygen as a substrate to add hydroxyl groups to many other proteins with known functions, and current research is uncovering the regulation of these targets by proline hydroxylation. Flies and worms have a single prolyl hydroxylase, attesting to the evolutionary conservation of this oxygen-dependent signaling pathway in defense against hypoxic stress.

The E3 ubiquitin ligase that adds the ubiquitin chain to Hif-1α was discovered not in a study of oxygen sensing but of kidney tumors. Early work showed that certain kidney tumors had inactivating mutations in a tumor suppressor gene, the von Hippel-Lindau (VHL) protein and that these tumors had an abnormally increased number of capillaries surrounding them because they were producing enhanced amounts of VEGF. Trying to identify the function of the VHL protein, investigators soon found that it was in a complex with other proteins that were known to be part of an E3 ubiquitin ligase enzyme. This complex turned out to be the ubiquitin ligase that adds the ubiquitin chains to Hif-1α in which one or both proline residues was modified to hydroxyproline. Indeed, VHL was shown to directly bind to the two segments of the Hif-1α protein that contain a hydroxyproline, and tumor cells with VHL deficiency exhibited up-regulation of all known Hif-1α target proteins, including many enzymes in the glycolytic pathway. An enhancement of glycolysis was known to be important for the growth of many cancer cells; as we learn in Chapter 25, many cancer cells carry out glycolysis even in the presence of high oxygen levels. While producing less ATP per mole of glucose metabolized than does mitochondrial oxidative phosphorylation, aerobic glycolysis produces many intermediates that are siphoned off the glycolytic pathway as building blocks for amino acids and other molecules that are necessary for the rapid growth of cancer cells. ■

A Conserved Family of Oxygen-Sensitive Transcription Factors Found in Plants and Animals Is Regulated by Post-Translational Addition of an Arginine Residue

Like animal cells, plant cells can also become anoxic; often during flooding or waterlogging, cells inside seeds or meristems (see Chapter 22) can also suffer from reduced O_2 diffusion. Recent work has shown that plants such as rice, *Arabidopsis*, and barley respond to hypoxia by increasing the level of a group of oxygen-sensing transcription factors termed *group VII ethylene response factors (ERFs)*. Similar oxygen-sensing factors have been detected in human and other animal cells, indicating that this signaling pathway evolved very early in eukaryotic evolution. Like Hif-1α, ERF proteins promote the synthesis of proteins that enhance survival under low oxygen, including key enzymes in the glycolytic pathway that facilitate anaerobic metabolism, such as alcohol dehydrogenase and pyruvate decarboxylase (see Chapter 12).

ERF proteins all contain an N-terminal cysteine residue that undergoes an unusual series of enzyme-catalyzed reactions at ambient oxygen levels that targets them for degradation by the proteasome (Figure 21-8). The first step, the oxygen-sensing step, is catalyzed by an enzyme termed *cysteine dioxygenase* that binds O_2

and transfers its two oxygen atoms to the N-terminal cysteine residue, forming cysteine sulfinic acid. Note that this is a different reaction than catalyzed by the PHD2 enzyme, but like PHD2 this reaction only occurs at high oxygen levels. The N-terminal cysteine sulfinic acid, in turn, serves as a binding site for an enzyme termed *arginyl-tRNA-protein transferase (ATE)*. This enzyme catalyzes the transfer of the arginine residue from an arginyl tRNA to the amino group of the cysteine sulfinic acid. (Note that this is an unusual reaction in which an aminoacyl tRNA does not participate in ribosome-catalyzed protein synthesis.) Proteins with N-terminal arginine residues are unstable and are immediately subjected to ubiquitination and degradation in the proteasome. In fact, well before this oxygen-sensing pathway was discovered, researchers had defined the so-called N-end rule, in which the in vivo half-life of a protein is determined by the identity of its N-terminal residue. Primary destabilizing N-terminal residues were shown to be recognized directly by the ubiquitin targeting machinery, and proteins with an N-terminal arginine were known to be very unstable.

FIGURE 21-8 Degradation of ERF transcription factors at ambient oxygen levels. This pathway occurs in a similar fashion in both plants and animals. Step **1**: At ambient oxygen, but not at reduced oxygen levels, cysteine dioxygenase adds the two oxygen atoms from O_2 to the cysteine residue that is found on the N-terminus of all ERF proteins, forming an N-terminal cysteine sulfinic acid residue. Step **2**: The N-terminal cysteine sulfinic acid serves as a binding site for an arginyl-tRNA-protein transferase (ATE), which then transfers the arginine residue from an arginyl tRNA to the amino group of the cysteine sulfinic acid. Step **3**: An E3 ubiquitin ligase enzyme that uses as substrates

proteins with N-terminal arginine residues adds a ubiquitin chain to the ERF protein that (step **4**) triggers immediate degradation of it by the proteasome.

[Data from D. J. Gibbs and M. J. Holdsworth, 2020, *Cell* **180**(1):22–24.]

Thus at least two classes of oxygen-sensing transcription factors have evolved, ERFs and HIF-1α's. Both induce synthesis of proteins that help the cell or organism survive at low oxygen levels, and both are degraded at ambient oxygen levels by processes initiated by enzyme-catalyzed attachment of O atoms from O_2.

KEY CONCEPTS OF SECTION 21.4

Responding to Low Oxygen

- In metazoans, at low oxygen levels the transcription factor Hif-1α accumulates and induces the transcription of many genes that enable the cell or organism to survive this stress. Proteins that catalyze regulated and rate-limiting steps in the glycolytic pathway are induced in many body cells, and erythropoietin in certain kidney cells.
- At high oxygen levels the prolyl hydroxylase PHD2 transfers an OH group to two proline residues in Hif-1α leading to binding of the tumor-suppressor protein VHL, polyubiquitinylation by an E3 complex, and destruction by the proteasome (see Figure 21-7).
- Many plants and animals express a different family of oxygen-sensitive transcription factors that involves cysteine oxidation and post-translational addition of an arginine residue, leading to polyubiquitinylation and degradation (see Figure 21-8).

21.5 Responding to Elevated Temperatures

The heat-shock response is part of a general cellular response to the accumulation of unfolded proteins caused by one or more cellular stresses, including elevated temperature (giving rise to the name of the response). Other stresses that cause protein denaturation also induce the heat-shock response, such as oxidative stress (which causes oxidation of sulfur atoms in cysteine and methionine), hypoxia, heavy metals, ethanol, and other toxic substances. A similar mechanism induces high-level expression of roughly 50–200 genes in different organisms from archaea to cultured human cells, indicating that this response evolved early in eukaryotic evolution. The **heat-shock proteins** (or **HSPs**) encoded by these genes perform several processes that protect cells from the consequences of unfolding a large fraction of cellular proteins.

In this section, we will discuss two main actors in the heat-shock response. The accumulation of unfolded proteins is sensed by HSP70 proteins expressed at moderate levels in unstressed cells. If these molecular chaperones are unable to restore correct protein folding, a pathway is activated to induce further expression of HSP70 genes and other heat-shock genes that function to prevent aggregation of unfolded proteins. This gene expression program is mediated by the transcription factor HSF (*h*eat-*s*hock *f*actor). This protein is normally kept in check and is released when high

concentrations of unfolded proteins are present in the cell. Below, we will see how HSPs interact with unfolded proteins to restore the correct conformations, how the HSF transcription factor is activated, and how the heat-shock response is induced.

Before describing the details of the heat-shock response, we should note one of its most remarkable and surprising aspects: it is triggered by a temperature increase of just a few degrees. For human cells cultured at 37 °C (310 K), a shift in temperature to 42 °C (315 K) activates transcription of heat-shock protein genes to maximum levels, >100 times the rate in unstressed cells. Since the kinetic energy of molecules in solution is proportional to their temperature in K, this represents only a 1 percent increase in the kinetic energy of protein molecules. How does such a small increase in kinetic energy lead to maximum activation of heat-shock gene transcription? The answer to this puzzle is thought to result from the fact that proteins have evolved to be conformationally flexible at the normal growth temperature of the organisms in which they occur. This flexibility is necessary for the functions of many proteins, both structural and enzymatic. Consequently, most proteins have been optimized by evolution of their primary sequence to be only marginally stable at the normal growth temperature. A small increase in temperature can cause protein unfolding. Without the defenses against protein unfolding from induced heat-shock proteins, these regions of unfolded polypeptide can become entangled, leading to nonspecific protein aggregation and cell death. The heat-shock response that protects against this is triggered by the

large increase in the amount of unfolded polypeptide that results from an increase in temperature of only a few degrees.

The Heat-Shock Response Is Induced by Unfolded Polypeptide Chains

The most conserved heat-shock proteins are molecular chaperones that prevent the formation of nonspecific protein aggregates and assist unfolded proteins in refolding into their native structures. Humans express 11 small HSPs (<45 kDa) exemplified by HSP27. These bind to unfolded, hydrophobic polypeptides, inhibiting them from forming large multimolecular aggregates. The human genes most highly induced in response to elevated temperature encode a group of closely related proteins called *HSP70s*. These are among the most highly conserved protein chaperones throughout all kingdoms of life. The bacterial version, called *DnaK*, shares about 60 percent sequence identity with eukaryotic HSP70 proteins. HSP70s are found principally in the cytosol and in organelles, such as the ER, mitochondria, and chloroplasts. Under normal physiological conditions, HSP70s assist in the de novo folding of nascent and newly synthesized proteins (see Figure 3-19a). In humans, *HSPA8* (also known as *HSC70, "C"* for constitutive) serves this function and is expressed constitutively in all cells; it is not induced by heat shock. The two major HSP70s induced by heat shock, encoded by *HSPA1A* (also known as *HSP70-1*) and *HSPA1B (HSP70-2)*, are nearly

identical in sequence and are ~90 percent identical to HSC70. The two HSP70s are thought to function similarly; in the discussion below they will be referred to together as simply HSP70.

HSP70s (including HSC70) contain two domains, an ATPase domain and a protein-binding domain (see Figure 3-19a). When ATP is bound to the nucleotide-binding pocket in the ATPase domain, the protein-binding domain is held in an open conformation that binds a sequence of seven mainly hydrophobic amino acid residues in an extended conformation. Stretches of hydrophobic amino acids this long generally occur only in the hydrophobic core of properly folded proteins and in transmembrane α helices. Consequently, HSP70s bind unfolded polypeptides or unfolded regions in a polypeptide where such hydrophobic stretches are exposed. This initial binding is low affinity and reversible.

In the following discussion about the control of heat-shock gene transcription, we will be concerned primarily with this ATP-bound form of HSP70s. As discussed in Chapter 3, with the assistance of an *HSP40* co-chaperone, an HSP70 weakly bound to an unfolded region of the *client protein* hydrolyzes the ATP to ADP, resulting in a conformational change of the HSP70 protein-binding domain, so that it unfolds the bound region of the client protein into a conformation that is amenable to proper spontaneous refolding when it is released. ATP hydrolysis also results in very high affinity binding of the client protein. Then, with the assistance of a

nucleotide exchange factor, both the ADP and the client protein are released as ATP becomes bound by the HSP70 ATPase domain. This moves the protein-binding domain into its open conformation. The released, unfolded client polypeptide then has another opportunity to fold into the correct native conformation. Repeated cycles of binding, ATP-dependent unfolding, and spontaneous refolding of the released polypeptide may occur and even lead to the proper refolding of polypeptides in large aggregates.

The Heat-Shock Response Is Regulated Primarily by Related Transcription Factors in All Eukaryotes Called *Heat-Shock Factors*, Including HSF1 in Humans

When the amount of unfolded protein in the cell increases in response to heat shock, HSC70 and any HSP70 induced by heat shock associate with the unfolded regions of polypeptide generated and with any protein aggregates that have formed (Figure 21-9b). Nascent polypeptides still associated with ribosomes are generally the first proteins to unfold because the incomplete polypeptides have fewer stabilizing interactions than the complete protein (see Figure 21-9b). As a result, most of the HSC70 and HSP70s in the cell become associated with unfolded nascent polypeptides. It is this

depletion of free HSC70s and HSP70s that triggers the heat-shock response.

FIGURE 21-9 Regulation of the heat-shock response. HSF1 is inactivated by binding to free HSP70 that has a bound ATP. (a) Regulation of HSF1 by HSP70. Under normal physiological conditions of temperature and the absence of protein denaturants (*right*), most HSF1 is in a latent form complexed with HSC70–ATP in the cytoplasm. If the amount of unfolded protein in the cell increases substantially, most of the cellular HSC70 becomes associated with the denatured proteins. This releases HSF1 to form trimers that are imported into nuclei and activate transcription of genes with promoter proximal HSEs (*left*). (b) During heat shock, nascent polypeptides associated with ribosomes are generally the first to denature because they have fewer interactions stabilizing the correct fold than in full-length proteins. Regions of exposed stretches of hydrophobic amino acids and denatured protein aggregates are bound by the open protein-binding domain of HSP70-ATP, titrating HSP70-ATP away from HSF1 by mass action. The released HSF1 forms trimers that are bound by importins and transported into nuclei where they bind to HSEs and activate transcription of HSP genes, as diagrammed in (a). See A. E. Masser et al., 2019, *eLife* **8**:e47791.

As mentioned above, the heat-shock response involves the sharp increase in the levels of chaperone and other proteins. This is achieved via the release of the HSF1 transcription factor. In its activated form, HSF1 forms a trimer, and an α helix of each monomer interacts with the major groove of three successive alternating inverted repeats with the sequence nGAAn, where *n* denotes any nucleotide (e.g., nTTCnnGAAnnTTCn; Figure 21-9a). HSF-binding sites are known as *heat-shock elements (HSEs).* Virtually all genes activated by the heat-shock response have one or more HSEs in their promoter proximal region. An activation domain at the C-terminus of HSF1 activates transcription through interactions with the mediator complex and other co-activators, as described in Chapter 8. Studies of the *Drosophila Hsp70* gene led to the discovery of a pause in transcription approximately 50 bases downstream from the transcription start site of many genes in metazoans (see Figure 8-16). In *Drosophila* cells cultured at normal temperature, RNA polymerase II remains paused at this site. Following heat shock, HSF is activated and binds to promoter proximal HSEs of the heat-shock genes and stimulates polymerase release through activation of cyclin T-Cdk9 (see Figure 8-16). This results in a very rapid transcriptional response to protein denaturation since RNA polymerase is already engaged in transcription.

As the concentration of unfolded proteins increases following heat shock, the concentration of free HSC70 and HSP70 available to

interact with HSF1 drops precipitously. Since the interaction between HSP70s and HSF1 is reversible, HSF1 is released from HSC70 and HSP70s and is free to trimerize and interact with importins. Then it is transported into nuclei and binds HSEs, stimulating transcription of all genes with promoter proximal HSEs.

Recent studies using purified recombinant yeast HSP70 and derivatives of HSF1 strongly support the following model for heat-shock regulation of HSF1: before activation by heat shock, most HSF1 is located in the cytosol in a latent form associated with HSC70s, which are in excess over HSF1 (Figure 21-9a, *right*). HSC70 in its ATP-bound conformation binds reversibly to several regions in HSF through HSC70's open protein-binding domain that associates with extended, largely hydrophobic regions of polypeptide (Figure 3-19, step **1**). This reversible association of HSC70 with HSF1 inhibits HSF1 interactions with importins required for HSF1 nuclear import. In vertebrates, HSC70 also dissociates a large fraction of the HSF1 trimers into inactive HSF1 monomers bound by HSC70.

Importantly, there are HSEs in the promoter proximal region of the HSF1 gene itself, so *HSF1* is also a heat-shock activated gene. HSF1 mRNA and protein accumulate during extended heat shock, leading to increasing expression of heat-shock genes to the point that they become major cellular proteins. The process is reversed when human cells incubated at 42 °C for several hours, to maximally induce the heat-shock response, are returned to 37 °C. Transcription

of heat-shock genes returns to the level in unshocked cells within a few hours. This occurs because renaturation of unfolded polypeptides catalyzed by HSP70s and other protein chaperones induced by heat shock releases free HSP70s that then associate with activated HSF1, inhibiting its DNA-binding and transcriptional activation and thus repressing transcription of all heat-shock genes.

In the immediate period following extended heat shock, HSF1, HSP70s and other protein chaperones induced by heat shock remain at high concentration. This makes the previously heat-shocked cells resistant to higher temperatures and resistant to higher concentrations of denaturing agents, such as ethanol, than naive cells cultured in normal medium continuously at 37 °C. In this way, the heat-shock response helps cells to both survive acute protein denaturation and also adapts cells to an environment in which they are exposed to denaturing conditions repeatedly. This also explains why cells initially treated with a denaturing agent, such as ethanol, are more resistant to alternative denaturing agents, such as elevated temperature, than cells that were continuously cultured at 37 °C and that did not induce expression of HSPs.

KEY CONCEPTS OF SECTION 21.5

Responding to Elevated Temperatures

- The heat-shock response is induced by unfolded polypeptide chains generated by various conditions, including elevated temperature.

- Most proteins are evolutionarily optimized to be only marginally stable at the normal growth temperature so that they have the flexibility to perform their functions. Consequently, an increase in temperature of only a few K is sufficient to unfold a large fraction of polypeptide chains. Nascent polypeptides associated with ribosomes are especially sensitive to denaturation because they generally have fewer interactions holding them in the proper conformation than the full-length protein (see Figure 21-9b).
- Closely related heat-shock transcription factors (HSF1 in humans) are expressed in all eukaryotes and activate transcription of heat-shock genes when a substantial fraction of unfolded polypeptides accumulate. The heat-shock proteins encoded by these genes bind to and prevent aggregation of unfolded regions of polypeptides and assist in refolding proteins into their proper conformations. HSF1 binds to heat-shock response elements in the DNA sequences of promoter proximal regions and activates high levels of transcription.
- At normal temperature, RNA polymerase II remains paused at approximately +50 in the many heat-shock genes, until HSF is activated, binds to promoter proximal HSEs, and stimulates polymerase release through activation of cyclin T-Cdk9 (see Figure 8-16). This results in a very rapid transcriptional response to protein denaturation, since RNA polymerase is already engaged in transcription and does not have to go through the steps of chromatin decondensation and preinitiation complex assembly before transcription begins.
- At elevated temperature, HSP70s are sequestered away from HSF1 because most HSP70s bind to unfolded regions of polypeptides (see Figure 21-9b). This allows HSF1 to trimerize and become transported into nuclei, where it binds to HSEs in promoter proximal regions of heat-shock genes. HSF1 then stimulates release of the paused RNA polymerase II and high rates of transcription re-initiation of heat-shock genes.

21.6 Sensing Night and Day: Circadian Rhythms

The Earth rotates around an axis passing through the North and South Poles on a 24-hour cycle, with night facing away from and day facing toward the sun. To adapt to this, all organisms have evolved endogenous circadian rhythms that are modulated by dark and light. The word *circadian* derives from *circa diem*, Latin for "about a day," reflecting the fact that circadian rhythms repeat approximately every 24 hours. The study of the biology of circadian rhythms is called *chronobiology*, from the Greek *chronos*, which means "time."

Perhaps the most familiar behavioral circadian rhythm for human and nonhuman animals is the sleep-wake cycle, which for humans and other diurnal animals follows night (sleep) and day (wake). Circadian rhythms are driven by internal molecular clocks within cells that oscillate over a 24-hour period. In addition, there is a process by which these endogenous clocks can be reset by the external cues, called *zeitgeber*, German for "time giver." In fact, the definition of a circadian rhythm requires that it include an endogenous, self-running clock that can be entrained by external cues. The sleep-wake cycle in humans meets both of these criteria. In 1938, two researchers did an experiment in which they spent 32 days in a cave in Kentucky and monitored their sleep-wake cycle. They found that even in the absence of any light, they continued to exhibit circadian sleep-wake rhythms, although over time the

rhythms shifted relative to the actual onset of dark and light in the outside world. Once they left the cave, their sleep-wake cycle resynchronized to the external dark-light cues. As this early experiment demonstrated, human circadian rhythms are not only intrinsic and self-running, but they are also entrainable by external cues. Jet lag provides another commonly experienced example of our internal yet modifiable biological clock: after traveling to a different time zone, individuals usually continue to follow their usual, intrinsic sleep-wake pattern, but within a few days adapt to the dark-light cycle of their new environment.

All eukaryotes and some prokaryotes exhibit circadian rhythms. In addition to sleep-wake cycles in humans and other organisms, examples of biological processes that exhibit circadian rhythms include the release of hormones such as insulin and glucagon (described in Section 21.1), feeding behavior in rodents, leaf movement in plants, locomotor activity in flies, and even nitrogen fixation in cyanobacteria. In each case, the behavior involves an intrinsic molecular clock within cells that can be entrained by the external environment. While the most powerful external cue, or zeitgeber, is the dark-light cycle, other cues that impact circadian rhythms include medication, temperature, social interactions, exercise, eating and drinking, and weather. Remarkable progress has been made in understanding the genes and molecules that constitute the molecular clock and the pathways and cues that entrain that clock, together giving rise to circadian rhythms. In this section, we will first consider the mechanisms that give rise to the

molecular clock and then turn our attention to the question of how external cues modulate the molecular clock to entrain circadian rhythms.

The Circadian Clock in Most Organisms Relies on a Negative Feedback Loop

The molecular dissection of circadian clocks provides one of biology's most powerful demonstrations of the genetic basis of behavior, advances that were recognized by the 2017 Nobel Prize in Physiology or Medicine. The initial discoveries on circadian rhythms were conducted in the fruit fly *Drosophila melanogaster*, which, like all organisms, exhibits circadian rhythms in many behaviors. In a series of genetic screens done in the early 1970s, scientists searched for mutant flies that had alterations in their circadian rhythms. This led to the identification of a gene they called *period* or *per*, because mutations altered the periodicity of the circadian rhythm without impacting any other aspect of *Drosophila* physiology. The discovery of the *per* gene opened a field of study that in turn elucidated an entire oscillatory molecular feedback loop that takes ~24 hours to complete. This feedback loop involves transcriptional and post-translational regulatory steps that together form a biological clock that is present in almost all eukaryotic cells and in some prokaryotic cells.

As shown in Figure 21-10, the central components of the clock in *Drosophila* cells constitute a negative feedback loop in which clock genes are regulated by their own protein products. The components of this loop include: two transcriptional repressors, PER and TIMELESS (TIM), encoded by the *per* and *timeless (tim)* genes; two transcriptional activators, CLOCK (CLK) and CYCLE (CYC), encoded by the *clock (clk)* and *cycle (cyc)* genes; and several kinases and E3 ubiquitin ligases. CRY, a cryptochrome (a protein with an attached flavin group that undergoes a conformation change when it absorbs blue light), encoded by the *cry* gene, plays a key role. TIM and PER levels cycle every 24 hours; they accumulate during the day and are degraded during the night.

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

FIGURE 21-10 Molecular circadian clock in eukaryotes. The circadian clock in *Drosophila melanogaster* cells consists of two transcriptional repressors, PER and TIM, two transcriptional activators, CLK and CYC, several kinases (including the DBT kinase) and E3 ligases, and the light-sensitive protein CRY. During the day CLK and CYC dimerize to stimulate the transcription of PER and TIM, but TIM and PER proteins both undergo regulated degradation. In the case of PER, it is phosphorylated by the DBT kinase during the day, leading to ubiquitylation by E3 ligases and degradation. Concentrations of PER and TIM peak at dusk, when TIM binds to PER and protects it from DBT phosphorylation and subsequent degradation. During the night, the TIM-PER dimer is transported into the nucleus where it binds to CLK and CYC, blocking their ability to stimulate transcription of the *per* and *tim* mRNAs throughout the night. At dawn, the light triggers a conformational change in the CRY-photosensitive

protein, which then binds to TIM, releasing it from PER, and from CLK and CYC. CRY binding to TIM triggers its ubiquitylation and degradation, and in the absence of TIM binding, PER also undergoes DBT-mediated phosphorylation, ubiquitylation, and degradation. This now allows CLK and CYC to bind to the *per* and *tim* promoters to induce their transcription. This entire cycle takes approximately 24 hours to complete.

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

FIGURE 21-11 Molecular circadian clock in prokaryotes. (a) The circadian clock in the cyanobacteria *Synechococcus elongatus* consists of three proteins, KaiA, KaiB, and KaiC. KaiC possesses intrinsic kinase and phosphatase activity. At dawn, KaiC exists in a de-phosphorylated state. After binding of KaiA, however, its kinase activity is activated and it autophosphorylates itself at two residues. One of the residues in KaiC slowly becomes de-phosphorylated, leading to the binding of the KaiB protein and release of KaiA. KaiB binding to KaiC inhibits its kinase activity, leading to fully de-phosphorylated of KaiC and release of KaiB. (b) This entire cyanobacteria cycle can be reconstituted in a test tube, where the phosphorylation state of KaiC undergoes a 24-hour oscillation, as shown in an immunoblot, in which the phosphorylation form of KaiC (P-KaiC) is separated from its nonphosphorylated

form (NP-KaiC). (c) Quantification of the ratio of P-KaiC to NP-KaiC in part (c) reveals a 24-hour circadian rhythm.

[Parts (b) and (c) republished with permission from American Association for the Advancement of Science, from M. Nakajima et al., 2005, "Reconstitution of Circadian Oscillation of Cyanobacterial KaiC Phosphorylation In Vitro," *Science* **308**(5720):414–415; permission conveyed through Copyright Clearance Center, Inc.]

CLK and CYC are both basic helix-loop-helix transcription factors (see Section 8.4) that form a heterodimer and during the day bind to the promoter regions of the *per* and *tim* genes to induce their expression. The levels of PER and TIM proteins are low when their transcription is initially induced because they undergo protein degradation. In the case of the PER protein, its stability is regulated by phosphorylation by the DOUBLETIME (DBT) kinase, which in turn leads to the recruitment of an E3 ubiquitin ligase that targets PER for proteasome-mediated degradation.

The concentrations of PER and TIM peak in the evening, with TIM binding to and stabilizing PER. The TIM-PER complex is then phosphorylated by another set of kinases, which promotes nuclear translocation of the TIM-PER complex. In the nucleus, the TIM-PER complex associates with the CLK-CYC dimer, thereby repressing its transcriptional ability and inhibiting expression of their own *per* and *time* genes throughout the night.

CRY is a flavin-containing photosensitive protein (see Figure 2-33), and light exposure at dawn triggers a conformational change in CRY,

followed by CRY binding to TIM. Upon association with CRY, TIM is ubiquitinated and degraded by the proteasome, freeing up PER to once again be phosphorylated by DBT, ubiquitinated, and degraded. Degradation of TIM and PER relieves the inhibition of CLK-CYC and thereby reactivates the transcriptional activation of PER and TIM during the day.

This feedback mechanism occurs over an approximately 24-hour period, constituting the molecular circadian clock. In simplistic terms, the clock involves two transcriptional repressors, PER and TIM, whose stability is regulated by phosphorylation, ubiquitination, and degradation. PER and TIM repress expression of their own genes by binding to and inactivating the CLK and CYC transcriptional activators (which promote expression of the *per* and *tim* genes).

The Circadian Clock in Bacteria: A Different Solution

Most, but not all, molecular clocks achieve oscillation through the type of transcriptional feedback loop shown in Figure 21-10. In the cyanobacteria *Synechococcus elongatus,* the clock is composed of three proteins, *KaiA, KaiB,* and *KaiC*, and the oscillatory feedback loop involves a series of post-translational modifications to KaiC (Figure 21-11a). KaiC has intrinsic kinase and phosphatase activities.

As an isolated protein, the phosphatase is most active and KaiC exists mostly in its de-phosphorylated state. KaiA binding to KaiC inhibits the phosphatase activity and promotes the kinase activity, leading to autophosphorylation of KaiC at two sites. KaiC then slowly de-phosphorylates itself at one of the two sites, and the singly-phosphorylated KaiC now binds to KaiB. KaiB inhibits the kinase activity of KaiC, such that over time KaiC returns to its de-phosphorylated state. This simple feedback loop, consisting of a single protein (KaiC) that alternately phosphorylates and de-phosphorylated itself depending on its protein-protein interactions (with KaiA and KaiB) can actually be fully reconstituted in a test tube (Figures 21-11b and c), creating a 24-hour cycle of phosphorylated and de-phosphorylated KaiC!

Suprachiasmatic Nucleus: The Master Clock in Mammals

While molecular clocks are distributed in cells throughout the body, the **suprachiasmatic nucleus (SCN)**, a collection of neurons in a region of the brain called the *hypothalamus* (Figure 21-12a), functions as a master clock or central pacemaker for circadian rhythms in mammals. Indicative of the central role of the SCN in synchronizing all clocks, destruction of the SCN abolishes all regular circadian rhythms and transplantation of an SCN into SCN-ablated animals restores circadian rhythms. Neurons in the SCN receive

input from photoreceptor-containing ganglion cells in the retina. This information is then relayed by SCN neurons to downstream neurons and glands to trigger the release of hormones that in turn regulate an array of biological rhythms. For example, light and dark regulate the release of melatonin from the pineal gland. Melatonin production, a hormone believed to promote sleep onset, is inhibited by light and stimulated by darkness, with the light and dark information being relayed from the retina to the SCN to the pineal gland. As another example, light activates release of cortisol from the adrenal gland. Cortisol, a stress hormone, is highest in daytime and regulates many physiological processes, including blood pressure, blood glucose levels, and inflammation.

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

FIGURE 21-12 The suprachiasmatic nucleus (SCN) is the master clock in mammals. (a) Light is detected by cells in the retina and relayed via a neuronal pathway (lavender) to the suprachiasmatic nucleus (SCN) in the brain. The SCN in turn sends signals to other neuronal centers and glands to induce signals that regulate molecular clocks throughout the body. One of these signals is to the pineal gland, which releases melatonin, a hormone that modulates the onset of sleep. (b) Individual neurons isolated from the SCN show 24-hour oscillating rhythms in action-potential firing (see Chapter 23 for discussion of action potentials) that persist for as long as the neurons are maintained in culture.

[Part (b) Data from D. K. Welsh et al., 1995, *Neuron* **14**:697–706.]

In addition to relaying information about light and dark, the SCN possesses a particularly robust intrinsic molecular clock. The SCN consists of a heterogeneous cluster of about 10,000 neurons on each side of the brain. When SCN neurons are isolated and placed in culture, they show circadian rhythms in levels of free calcium in the cytosol and electrical firing that follows a 24-hour period for as long as they are maintained in culture (Figure 21-12b). In addition to these cell-autonomous circadian rhythms, signaling between neurons in the SCN demonstrate circadian rhythms, such that the circuit properties of the SCN are critical to the generation of circadian rhythms throughout the body.

Recent research has revealed the impact of circadian rhythms on many aspects of cell biology, from transcriptional, translational, and post-translational regulation to the dynamics of intracellular organelles, to cell differentiation, and to cell death. In research

laboratories, this realization has motivated many scientists to consider the time of day during which they conduct their experiments. Circadian rhythms are also clinically important. In addition to primary diseases of circadian rhythms, which include narcolepsy (a syndrome characterized by daytime sleepiness and involuntary, uncontrollable sleep episodes) and sleep disorders in which the phase of sleep is altered, many other diseases are accompanied by alterations in circadian rhythms. For example, nearly 25 percent of individuals with Alzheimer's disease have significant sleep disorders, and up to 75 percent of children with autism spectrum disorders have sleep disturbances. Increased molecular and cell biological insights into the functioning of molecular clocks and the mechanisms by which external cues entrain these clocks are likely to have important therapeutic implications for these clinical disorders. ■

KEY CONCEPTS OF SECTION 21.6

Sensing Day and Night: Circadian Rhythms

- All organisms exhibit ~24-hour circadian rhythms that are driven by molecular clocks within cells and that can be reset by external cues such as light and dark.
- A negative feedback loop in which clock genes are regulated by their own protein products is conserved from flies to humans. This feedback loop consists of two transcriptional repressors, PERIOD and TIMELESS, two transcriptional activators, CLOCK and CYCLE, and several kinases and E3 ubiquitin ligases. PERIOD and TIMELESS levels cycle every 24 hours, accumulating during the day and being degraded at night.
- Bacteria have a different circadian clock, consisting of three proteins, KaiA, KaiB, and KaiC, that form a transcriptional feedback loop that oscillates on a 24-hour cycle.

- In mammals, the suprachiasmatic nucleus (SCN) in a region of the brain called the *hypothalamus* serves as a master clock or central pacemaker. Ablation of the SCN abolishes all regular circadian rhythms.

21.7 Sensing and Responding to the Physical Environment

We learned in Chapters 16 and 17 how cells coordinate their activities by communicating with each other through receptors that bind soluble molecules secreted by a signaling cell or signaling proteins bound to the plasma membrane of a neighboring cell. Earlier in this chapter, we saw how cells regulate their metabolism and gene-expression patterns by sensors that respond to changes in many small molecules in their environment, as well as to changes in temperature and light. Cells also perceive their microenvironment through physical and mechanical cues (mechanotransduction) from the extracellular matrix (ECM) in which they are imbedded and by tension across intercellular adherens junctions generated from the indirect connections of these junctions to the actin cytoskeleton (see Figures 20-1 and 20-38). In this section, we discuss the Hippo pathway, a protein kinase signaling cascade conserved in all metazoans that senses and integrates these cues about the physical properties of the ECM and modulates cell growth and differentiation in response. As an example, during development, cells proliferate and differentiate to generate organs of specific sizes, and we will see how mutations in this pathway can result in excessive organ growth and how the Hippo pathway regulates the expression of multiple genes involved in growth control and differentiation. Abnormalities in this pathway contribute to many developmental disorders and generation of many types of cancers.

The Hippo Kinase Cascade Pathway in *Drosophila* and Mammals

The Hippo kinase pathway (Figure 21-13a) is conserved in all metazoans and their closest unicellular relatives, suggesting that it evolved before multicellularity. The discovery of the Hippo pathway came from studies by *Drosophila* geneticists searching for genes that control cell replication, genes now known as *tumor suppressors* (see Chapter 25). Examination of F_2 progeny derived from flies treated with a mutagen (see Figure 6-4) revealed that homozygous recessive mutations in a gene named *Hippo* resulted, as mentioned previously, in abnormally fat larvae that resemble a small hippopotamus, leading to the name of the gene. Further examination revealed that this phenotype was due to the growth of an abnormally large fat body, the *Drosophila* larva physiological equivalent of the vertebrate liver. Isolation and characterization of other *Drosophila* mutants with a similar homozygous recessive phenotype led to identification of genes encoding the core components of the Hippo pathway, heterodimeric protein kinases Hpo-Sav and Wts-Mats, which regulate the nuclear import of the transcriptional co-activator Yki (Figure 21-13a). Once imported into the nucleus, Yki activates transcription by binding to a sequence-specific DNA-binding protein encoded by *Sd,* which does not affect transcription in the absence of Yki. Later in this section, we learn about some of the many genes involved in cell proliferation and differentiation induced by the

human orthologs of Yki, called *YAP* and *TAZ*, and the human counterparts of *Drosophila Sd*, DNA-binding proteins TEAD 1 to 4.

FIGURE 21-13 The Hippo pathway has similar components and functions in *Drosophila* and mammals. (a) Proteins with orthologous functions in the Hippo pathway in *Drosophila*

and humans are indicated in italics and regular fonts, respectively. Arrows indicate activation of the downstream signaling component; see text for details. (b, c) Consequences of overexpression during embryogenesis of Yki in *Drosophila* wing imaginal disk (b), or of YAP in mouse liver (c) during embryogenesis. Normal tissues are shown to the left and tissues overexpressing Yki or YAP are shown to the right.

[Parts (b) and (c) republished with permission from Elsevier, from D. Pan, 2010, "The Hippo Signaling Pathway in Development and Cancer," *Dev. Cell* **19**(4):491–505; permission conveyed through Copyright Clearance Center, Inc.]

When the Hippo pathway is active, activated Hpo-Sav kinase phosphorylates and activates the Wts-Mats protein kinase, which then phosphorylates and inactivates the Yki transcriptional co-activator. Yki phosphorylated at specific serine residues is inactive as a transcriptional co-activator because it is bound by a class of *14-3-3 proteins* anchored in the cytoplasm (see Chapter 16) that bind phosphoserine and closely related phosphothreonine residues, preventing nuclear import of Yki.

The Hippo pathway is highly conserved in mammals (see Figure 21-13a), except that there are duplicates of the orthologous *Drosophila* genes. Human genes *MST1* and *MST2* are closely related to the orthologous *Drosophila Hpo* gene, encoding the catalytic subunit of the first protein kinase in the pathway. *LATS1* and *LATS2* are both orthologous to *Drosophila Wts* and encode the catalytic subunit of the second protein kinase in the pathway. And *YAP* and *TAZ* are ~60 percent identical in amino acid sequence and are both orthologs of the *Drosophila* transcription factor gene *Yki*. As discussed in Chapter

7 for β-globin gene family members, the proteins encoded by these duplicated and diverged Hippo pathway genes probably have similar but somewhat specialized functions. Inactivation of the Hippo pathway leads by default to nuclear import of the YAP/TAZ transcriptional co-activators, directed by their nuclear localization signals (NLSs). This leads to transcriptional activation of genes that have TEAD transcription factors prebound to enhancers that regulate them. This requirement for pre-binding of TEAD factors for gene activation by the imported YAP and TAZ co-activators determines which genes respond to regulation of Hippo signaling in different cell types.

The functional similarity between the Hippo pathway in *Drosophila* and mammals was dramatically demonstrated by experiments in which *Drosophila Yki* or the human *YAP* gene were overexpressed in cells in developing embryos. Overexpression of *Yki* in the *Drosophila* wing imaginal disc that normally develops into a wing during larval morphogenesis led to a great increase in the size of the imaginal disk, while the overall morphology of the developing organ was much less affected (Figure 21-13b). Analogously, overexpression of YAP in the developing mouse liver led to a greatly increased size of the liver compared to normal, but the overall morphology of the developing organ was near normal (Figure 21-13c). Further analysis showed that increased organ size in both *Drosophila* and mice was due to an increase in the number of cell divisions and a decrease in apoptosis in the developing organs. Further, YAP and TAZ are

considered to be oncogenes (see Chapter 25) because they are expressed at much higher than normal level in several types of human cancers where they likely contribute to oncogenesis by stimulating cell cycling (see Chapter 19) and inhibiting apoptosis (see Chapter 22).

Regulation of the Hippo Kinase Cascade by Cell Interactions with the Extracellular Matrix and by Tension on Actin Filaments

We learned in Chapter 4 that most types of animal cells will grow in culture only when attached to a solid surface. Many cells secrete extracellular matrix proteins such as fibronectin and collagen that stick to the surface of the plastic or glass culture dish and that in turn bind to integrins on the cell surface and allow the cell to spread on the culture dish. Evidence that the Hippo pathway, and consequently the nuclear localization of YAP and TAZ, is regulated by cellular interactions with the ECM was observed when wild-type human epithelial and mesenchymal stem cells were cultured on either a stiff or a soft surface (Figure 21-14a). Stiffness of the substratum is measured in units of pressure, kilopascals (KPa), required to deform its shape. At high stiffness (40 KPa) comparable to a glass coverslip routinely used to culture a monolayer of cells for immunofluorescence studies, the Hippo pathway was off and YAP

was nuclear. However, at low-substrate stiffness (0.7 KPa) the Hippo pathway was on and YAP was primarily cytoplasmic (see Figure 21-14a).

EXPERIMENTAL FIGURE 21-14 Regulation of Hippo pathway activity by physical properties of the ECM. (a) YAP localization in mesenchymal stem cells attached to a stiff (40 KPa) or soft (0.7 KPa) substratum, as detected by immunofluorescence. TOTO3 is a fluorescent stain for DNA and shows the location of nuclei. (b) Influence of the area of a square of fibronectin on nuclear localization of YAP and TAZ (both immunostained green).

(c) Summary of the influence of substrate stiffness and the area of cell spreading on assembly of actin stress fibers and YAP/TAZ subcellular localization.

[Parts (a) and (b) republished with permission from Springer Nature, from S. Dupont et al., 2011, "Role from YAP/TAZ in Mechanotransduction," *Nature* **474**:179–183; permission conveyed through Copyright Clearance Center, Inc.; Images courtesy of Sirio Dupont.]

In another revealing experiment, mesenchymal stem cells cultured from an early mouse embryo were plated on successively smaller squares of fibronectin dried onto a surface that cells do not otherwise attach to (Figure 21-14b). Individual cells spread only on the patches of fibronectin. At areas $>2025\ \mu m^2$ where the cell could spread out to near the area it covers on a continuous surface of fibronectin, YAP was nuclear, indicating that the Hippo pathway was off. However, in cells plated on smaller fibronectin squares of only $300\ \mu m^2$ where they could not spread out, YAP was primarily cytoplasmic (see Figure 21-14b), indicating that the Hippo pathway was active, leading to phosphorylation of YAP and TAZ and their retention in the cytoplasm. These experiments revealed that the activity of the Hippo pathway responded to the physical properties of the ECM and the area of cell adhesion (Figure 21-14c).

We learned in Chapter 17 that interactions of actin filaments with proteins attached to the plasma membrane is important for many aspects of cell adhesion. Indeed, cells that spread out on a stiff substratum contained extensive actin stress fibers visualized by staining with the fluorescently labeled fungal toxin phalloidin (Figure 21-15a). These are the cells in which the Hippo pathway was

off, as indicated by their nuclear YAP (see Figure 21-14a). In contrast, no actin stress fibers were observed in cells plated on a soft substratum (see Figure 21-15a); in these cells Hippo signaling was active, as indicated by cytoplasmic YAP (see Figure 21-14a). This correlation suggested that actin stress fibers somehow inhibit the Hippo pathway, leading to nuclear import of YAP that is not bound by cytoplasmic 14-3-3 proteins. Further experiments using the fungal toxin Latrunculin, which disrupts actin filaments, showed that actin fibers are indeed required for inhibition of Hippo signaling and nuclear localization of YAP (Figure 21-15b).

EXPERIMENTAL FIGURE 21-15 Regulation of Hippo pathway activity by tension on actin filaments. (a) Visualization of actin stress fibers with fluorescently labeled (green) phalloidin, a fungal toxin that binds actin filaments, but not actin monomers, in mesenchymal stem cells attached to a stiff (40 KPa) or soft (0.7 KPa) substratum. (b) Actin stress fibers are required for YAP nuclear localization. E1AKD293 cells are flattened against the substratum by tension on actin fibers running from apical to basal adherens junctions. The tension results from myosin motor proteins that move actin fibers extending from apical adherens junctions past actin fibers extending from basal adherens

junctions (see Chapter 17). This flattens the whole cell against the substratum, including the nucleus, making it appear large when viewed from the top (control). Thirty minutes after addition of Latrunculin B (LatB) to the media, actin cables were dissociated into actin monomers and nuclei took on a globular morphology that appeared much smaller when viewed from the top. In the absence of actin fibers, the Hippo pathway was on and YAP was sequestered in the cytoplasm.

The Hippo Pathway and Early Embryogenesis

The Hippo pathway is essential for many steps in development including the very first example of cellular differentiation during embryogenesis in mammals, the differentiation of cells on the surface of a 16–32 cell embryo, called a *morula*, into trophectoderm cells (see Figure 22-2). The inner cells of the morula remain undifferentiated and divide to form the inner cell mass of the early blastocyst that later develops into the embryo itself. The outer trophectoderm is required for implantation of the blastocyst in the uterine epithelium; it will later form extraembryonic tissues including the embryonic portion of the placenta (see Figure 22-3).

The Hippo pathway is active only in the inner cells of the morula; these are the cells that are surrounded on all sides by other cells and connected to them by adherens junctions (Figure 20-14e; Figures 21-16a and b). In these cells, YAP and TAZ are phosphorylated by the LATS kinase and retained in the cytoplasm (Figure 21-16a). In contrast, the outer cells of the morula have a free surface not attached to other cells. Under this segment of the plasma membrane are long filaments of F-actin, and as we will see this causes the Hippo pathway to become inactive. As a result, YAP/TAZ are imported into the nucleus where, together with a TEAD (see Figure 21-13a), they activate transcription of genes that initiate the trophectoderm differentiation program.

FIGURE 21-16 Regulation of the Hippo pathway in the morula by the subcellular localization of angiomotin. (a) Active Hippo signaling in the inner cells of the morula is indicated by the cytoplasmic localization of both phospho-YAP (*upper* panel) and total YAP (*lower* panel). In the outer cells, the Hippo pathway is off and YAP is unphosphorylated and nuclear. (b) Diagram of angiomotin (Amot) associated with adherens junctions on all cell surfaces of the inner cells (*lower panel*) and with the apical actin fibers in the outer cells (*upper panel*). In inner cells, association of Amot with Nf2 at adherens junctions stimulates Amot phosphorylation by LATS1 and 2, activating the Hippo pathway. In the outer cells,

sequestration of Amot at the apical surface inactivates Hippo signaling. (c) Immunofluorescent staining of Amot in the morula demonstrating its localization to all surfaces of the two inner cells shown and its sequestration to the apical surface of outer cells. (d) Summary of Hippo pathway activity and YAP nuclear localization in inner and outer cells of the morula.

[Part (c) republished with permission from John Wiley & Sons, Inc., from H. Sasaki, 2017, "Roles and Regulations of Hippo Signaling During Preimplantation Mouse Development," *Dev., Growth Differ.* **59**:12–20; permission conveyed through Copyright Clearance Center, Inc.]

In the morula, Hippo pathway signaling is controlled by an actin-binding protein called *angiomotin* (*Amot*; Figure 21-16b). In the inner cells, Amot is associated with the adherens junctions present on all surfaces of the cell (Figure 21-16c). The interaction between Amot and adherens junctions requires another junction-associated Hippo pathway component, neurofibromatosis 2 (Nf2), discussed below. In this adherens-junction-associated protein complex, a specific Amot serine residue becomes phosphorylated by the Hippo pathway protein kinases LATS1 and 2. In these preimplantation embryos, the phosphorylation of Amot stimulates phosphorylation of YAP/TAZ by LATS1/2, causing retention of YAP/TAZ in the cytosol.

Amot proteins (three paralogs in mice and humans) have an F-actin binding and polymerizing activity, and the Amot serines phosphorylated by LATS1/2 are in their actin-binding domain. Phosphorylation of Amots at these sites inhibits their ability to bind F-actin and enhances their phosphorylation by LATS1/2. This enhanced Amot phosphorylation stimulates Hippo signaling at adherens junctions (see Figure 21-16b), maintaining cytoplasmic

sequestration of YAP/TAZ in the inner cells of the morula (see Figure 21-16a). However, in the outer cells of the 16–32 cell embryo, cell polarization through the Par-aPKC system (see Chapter 22) induces assembly of a thick band of cortical actin filaments at the apical surface of the cell, where adherens junctions do not form because there are no neighboring cells. In these outer cells unphosphorylated Amot is sequestered away from the adherens junctions by binding to the cortical actin filaments. Consequently, Amot does not get phosphorylated by LATS, the Hippo pathway is inactive, and YAP/TAZ are imported into the nucleus (Figure 21-16d). In these cells nuclear YAP/TAZ together with TEAD (see Figure 21-13a) activate transcription of the homeodomain gene *Cdx2* and the zinc-finger transcription factor *Gata3,* which in turn initiate the developmental program of trophectoderm cells. In this way, cell-cell interactions via E-cadherins on the outside of the plasma membrane control Hippo signaling in the cytoplasm.

The experiments in Figures 21-14 and 21-15 indicate that the signals that control the activity of the Hippo pathway are regulated by physical properties of the ECM, such as stiffness, the area of the interacting adhesive cell surfaces, and tension on the actin cytoskeleton. These in turn are controlled by the changing cellular and tissue environment during embryogenesis and later stages of development to control Hippo signaling and the proliferation and differentiation of progenitor cells in the developing embryo. Such adhesive and mechanical forces ultimately control the sizes and

morphology of tissues and organs during development and during tissue regeneration after injury.

Mutations that inactivate one allele of human NF2, a component of the Hippo pathway (see Figure 21-16b), cause abnormal growth of peripheral nervous system tissue in the dominant genetic disease neurofibromatosis type II. NF2 associates with the cadherin-associated protein α-catenin on the cytoplasmic side of adhesion junctions (Figure 20-14e). As noted above, a specific Amot serine residue becomes phosphorylated by Hippo pathway protein kinases LATS1 and 2 in these adherens junction-associated protein complexes (Figure 21-16b). In preimplantation embryos, this phosphorylation of Amot stimulates phosphorylation of YAP/TAZ by LATS1/2, causing sequestration of YAP/TAZ in the cytoplasm. Phosphorylation at this site also blocks Amot association with actin filaments. In patients with one inactivated NF2 gene, half the normal amount of the NF2 protein is expressed. This decreases the activity of the Hippo pathway leading to abnormally high activation by YAP/TAZ and excessive cell proliferation. ■

Much remains to be learned about how regulation of the Hippo pathway in response to tension on the actin cytoskeleton contributes to tissue size and morphology, although it is clear that the overall process helps to sculpt the size and shape of metazoan organs. Understanding Hippo pathway regulation is medically important because abnormalities in the Hippo pathway function

contribute to oncogenic transformation and the invasiveness and metastasis of human tumors. Deeper understanding of Hippo pathway regulation may allow the logical design of therapeutic interventions in these diseases.

KEY CONCEPTS OF SECTION 21.7

Sensing and Responding to the Physical Environment

- The Hippo protein kinase pathway controls the sizes and morphologies of several organs during embryonic development of metazoans.
- The Hippo pathway is also required for regeneration of damaged tissues and organs in many metazoan tissues capable of regenerating after injury.
- The core components of the pathway are two heterodimeric protein kinases (Hpo-Sav and Wts-Mats in *Drosophila*). The activity of the pathway is regulated by signals from adherens junctions, mechanical forces acting on the actin cytoskeleton, and other aspects of the physical properties of the cellular environment.
- The principal targets of the pathway are the transcriptional co-activators YAP and TAZ (in mammals). Phosphorylation of YAP/TAZ causes their cytoplasmic sequestration and consequently inactivation of their transcriptional co-activator function.
- In the absence of this phosphorylation, YAP/TAZ are imported into the nucleus where they bind to inactive TEAD transcription factors (in mammals) prebound to multiple cell-type-specific enhancers, leading to transcriptional activation of these genes. Because of this, nonoverlapping sets of genes are regulated by the Hippo pathway in different cell types, depending on where TEAD factors are bound.
- In many cell types, activation of the Hippo pathway promotes apoptosis and inhibits cell cycling, limiting tissue growth. Inactivation of the Hippo pathway stimulates cell replication and inhibits apoptosis, stimulating tissue growth.
- Abnormal regulation of the Hippo pathway contributes to the uncontrolled growth of several types of human cancers and also to invasion of normal surrounding tissue and metastasis by cancers because of abnormal regulation of the actin cytoskeleton.

Key Terms

autophagy
circadian clock (circadian oscillator)
effector proteins
feedback repression
glucagon
gluconeogenesis
GLUT4 storage vesicle (GSV)
heat-shock proteins (HSP)
heat-shock response
Hif-1α
Hippo pathway
homeostasis

insulin
mechanoreceptors
mTOR protein kinase
mTORC1
sensors
signal amplification
signal transduction pathways
SRE-binding proteins (SREBPs)
suprachiasmatic nucleus (SCN)

Review the Concepts

1. How are insulin and glucagon secretion in the pancreas regulated? How does each hormone affect blood glucose levels?
2. What is GLUT4, and how is it regulated by insulin?
3. What parts of the blood glucose regulation pathways are affected in type 1 diabetes? In type 2 diabetes?
4. List and briefly describe the anabolic signal transduction pathways activated by mTORC1. How do these pathways contribute to cell growth?
5. One of the signals that activates mTOR are levels of cytosolic amino acids. How does this pathway function?
6. To what class of proteins does Rheb belong? Where is Rheb found in cells? Explain the mechanisms that regulate Rheb and describe the downstream consequences when a cell accumulates active Rheb.

7. How do SCAP and SREBP proteins work to prevent the expression of genes containing sterol regulatory elements when sufficient cholesterol is present in the endoplasmic reticulum (ER) membrane?
8. Describe the changes that are triggered in the cell when the cholesterol levels in the ER membrane drop to less than 5 percent of the total ER lipids.
9. What is nSREBP? Where is it generated? What is its function?
10. The expression of what two types of proteins is induced in mammals by Hif-1α? How do these proteins contribute to survival under low-oxygen conditions?
11. How do an aspargine hydroxylase, a proline hydroxylase, and an E3 ubiquitin ligase keep Hif-1α in check under normal oxygen levels?
12. How are ERF proteins in plants kept in check at ambient oxygen levels?
13. Why are proteins so sensitive to very small changes in temperature?
14. What is the role of heat-shock proteins (HSPs) in the protein-folding process?
15. In unstressed cells, how do HSPs and heat-shock factor (HSF) proteins interact to keep the heat-shock response in check?
16. What are the key genes or proteins in the circadian clock in *Drosophila melanogaster?* How does a negative feedback loop play a role in the circadian clock?
17. Describe the circadian clock in cyanobacteria.

18. What is a zeitgeber? How would a zeitgeber affect an organism's circadian rhythms? What are some examples of a zeitgeber?
19. What role does the Hippo pathway play in flies and mammals?
20. Based on the experiments described in this section, explain how input about the extracellular matrix (ECM) is translated to the on or off state of the Hippo pathway. How is subcellular localization of pathway components involved?
21. How does the Hippo pathway play a role in differentiation of the inner and outer cells of the morula?

CHAPTER 22

Stem Cells, Cell Asymmetry, and Regulated Cell Death

Daniel E. Wagner and Peter W. Reddien, MIT, Whitehead Institute.

Pluripotent stem cells called *neoblasts* provide the cellular basis for regeneration in planarian flatworms. Shown is a colony of neoblasts (yellow, orange, and red), all derived from a single neoblast 14 days after regeneration of the tail was initiated by amputation; differentiating cells (blue), also derived from the single neoblast, are shown as well.

OUTLINE

22.1 Early Mammalian Development, Embryonic Stem Cells, and Induced Pluripotent Stem Cells
22.2 Stem Cells and Niches in Multicellular Organisms
22.3 Mechanisms of Cell Polarity and Asymmetric Cell Division
22.4 Cell Death and Its Regulation

Many descriptions of cell division imply that the parent cell gives rise to two daughter cells that look and function exactly like the parent cell. In other words, they imply that cell division is **symmetric** and that the progeny have properties similar to those of the parent (Figure 22-1a). Many yeasts, fungi, and other single-celled eukaryotes do divide this way. Mature liver cells — hepatocytes — also divide symmetrically, each giving rise to two daughter hepatocytes.

FIGURE 22-1 Overview of the birth, lineage, and death of cells. Following growth, daughter cells are born as the result of symmetric or asymmetric cell division. (a) The two daughter cells resulting from symmetric division are essentially identical to each other and to the parent cell. Such daughter cells can subsequently have different fates if they are exposed to different signals. (b) The two daughter cells resulting from asymmetric cell division differ from birth and consequently have different fates. In some cases (*left*), both daughter cells are different from each other and from the parent cell. In others (*right*), one daughter cell is essentially identical to the parent and the other assumes a different fate. Asymmetric division is common when the parent cell is a stem cell and one of the daughters is also a stem cell; this allows the number of stem cells (yellow) to remain constant while the other daughter generates other cells (orange) that divide and then mature into one or more differentiated cell types. (c) A series of symmetric and asymmetric cell divisions, called a *cell lineage*, gives birth to each of the specialized cell types found in a multicellular organism and is under tight genetic control.

But if this were always the case, none of the hundreds of differentiated cell types and functioning tissues present in complex multicellular plants and animals would ever be formed. Differences among cells can arise when two initially identical daughter cells diverge upon receiving distinct developmental or environmental signals. Alternatively, the two daughter cells may differ from birth, with each inheriting different portions of the parent cell (Figure 22-1b). Daughter cells produced by such **asymmetric cell division** may differ in size, shape, or protein composition, or their genes may be in different states of activity or potential activity. The differences in these internal signals confer different fates on the two cells. In certain asymmetric cell divisions, one of the daughters is similar to the parent cell and the other forms a different type of cell.

In multicellular organisms, the formation of working tissues and organs, during both development and cell replacement, depends on specific patterns of mitotic cell divisions. A series of such cell divisions akin to a family tree is called a **cell lineage**. A cell lineage traces the birth order of cells as they progressively become more restricted in their developmental potential and *differentiate* into specialized cell types such as skin cells, neurons, or muscle cells (Figure 22-1c).

The development of a new metazoan organism begins with the *egg*, carrying a set of chromosomes from the mother, and the **sperm**,

carrying a set of chromosomes from the father. These *gametes*, or sex cells, are haploid because they have gone through meiosis (see Chapter 19). In the process called *fertilization*, they combine to create the initial single cell, the zygote, which has two sets of chromosomes and is therefore diploid. During embryogenesis, the zygote undergoes numerous cell divisions, both symmetric and asymmetric, ultimately giving rise to an entire organism. As we will see later in the chapter, many of the early divisions of the nematode *Caenorhabditis elegans* follow a *mosaic development* strategy, in which all of the early cell divisions are asymmetric and each daughter cell gives rise to a discrete set of differentiated cell types (see Figure 22-26).

However, the focus of the first section of this chapter is early mammalian development, quite different from that of *Caenorhabditis,* and the generation of embryonic stem cells. Both mouse and human embryos pass through an eight-cell stage; each of these cells can still form every type of tissue — both the embryo itself and the extraembryonic tissues — making all eight cells **totipotent**. At the 16-cell stage, this is no longer true: some of the cells have become committed to particular differentiation paths.

A group of cells called the *inner cell mass* will ultimately give rise to all tissues of the embryo proper, and another set of cells, the extraembryonic trophectoderm, will form the placental tissue (see Figures 22-2 and 22-3). Cells such as those in the inner mass that can

generate all embryonic tissues, but not extraembryonic tissues, are called **pluripotent**. As we will learn in Section 22.1, cells of the inner cell mass can be cultured in defined media, forming **embryonic stem (ES) cells**. ES cells can be grown indefinitely in culture, where they divide symmetrically, so that each daughter cell remains pluripotent and can potentially give rise to all of the tissues of an animal. We will discuss the use of ES cells in uncovering the transcriptional network of gene expression underlying pluripotency as well as in forming specific types of differentiated cells for research purposes or, potentially, as replacement parts for worn-out or diseased cells in patients.

For many years, animal cell differentiation was thought to be unidirectional, but recent data reveal that differentiation can be reversed experimentally. Through recombinant expression of specific transcription factors, several types of specialized, differentiated cells can be converted into another type of differentiated cell. Strikingly, introducing just a small number of the transcription factors that control the pluripotency of ES cells, under defined conditions, can over time convert at least some types of **somatic cells** into **induced pluripotent stem (iPS) cells** that have properties seemingly indistinguishable from those of ES cells. We will learn that, like ES cells, iPS cells have profound utility for experimental biology and medicine.

Many types of **stem cells** are important during both metazoan development and adult life. They are unspecialized cells that can

reproduce themselves as well as generate specific kinds of more specialized cells (see Figure 22-1b). Their name comes from the image of a plant stem, which grows upward, continuing to form more stem, while also sending off leaves and branches to the side. In the second section of this chapter, we explore several types of stem cells that differ in the variety of specialized cell types they can form, including those that give rise to germ cells, intestinal cells, and the variety of cell types found in blood. Unlike ES cells, the stem cells in adults are **multipotent**: they can give rise to multiple types of differentiated cells found in the organism but not all of them.

Some stem cells can undergo symmetric divisions in which both of the daughters are stem cells, thus increasing the number of stem cells. Many stem cells in animals and plants undergo asymmetric divisions in which one of the daughter cells is a stem cell; thus the numbers of stem cells can remain constant or can increase during the early stages of the organism's life. Many cells have life spans much shorter than that of the organism as a whole and so need to be constantly replaced. In mammals, for instance, cells lining the intestine and phagocytic macrophages live for only a few days. Stem cells are therefore important not only during development but also for replacement of worn-out cells in adult organisms. However, the numbers of certain stem cells often decreases as the organism ages, limiting their ability to replace certain outworn cells or tissues.

The zygote is totipotent in that it has the capacity to generate every cell type in the body as well as the supportive placental cells that are

required for embryonic development, but because the zygote does not *self-renew* (make more of itself), it is not considered a stem cell.

We have already mentioned that the diversity of cell types in an animal requires asymmetric cell divisions in which the compositions and fates of the two daughter cells differ. This process requires the parent cell to become asymmetric, or **polarized**, before cell division, so that the cell contents are unequally distributed between the two daughters. This process of polarization is critical not only during development but also for the function of many types of differentiated cells. For example, transporting epithelial cells, such as those that line the intestine, are polarized, with their free apical surface facing the lumen to absorb nutrients and their basolateral surface contacting the extracellular matrix to transport nutrients toward the blood (see Figures 11-30 and 20-1). Other examples include cells that migrate up a chemotactic gradient (see Figure 18-54) and neurons, which have multiple dendrites extending from one side of the cell body that receive signals and a single axon extending from the other side that transmits signals to target cells (see Chapter 23). Thus the mechanisms that cells use to polarize are important and general aspects of their function. Not surprisingly, these mechanisms integrate elements of cell signaling pathways (see Chapters 15 and 16), cytoskeletal reorganization (see Chapters 17 and 18), and membrane trafficking (see Chapter 14). In the third section of this chapter, we discuss how cells become polarized as

well as the mechanism of asymmetric cell division for maintaining stem cells and generating differentiated cells.

Death — of both organisms and the cells within them — is an essential part of life; without carefully regulated death, there could not be life. In the last section of this chapter, we discuss the regulation of cell death, termed **programmed cell death**. We learn that apoptosis, one type of evolutionarily conserved programmed cell death, is absolutely crucial for the formation and maintenance of many tissues (see Figure 22-1c). We also learn about a second type of programmed cell death, necroptosis, that vertebrates employ to kill virus-infected cells and thus block the spread of infection. Cells also die from environmental stresses or because they are no longer needed by the organism. Precise genetic regulatory systems, each with checks and balances, control cell death — just as other genetic programs control cell division and differentiation.

These aspects of cell biology — cell birth, the establishment of cell polarity, and programmed cell death — converge with developmental biology, and they are among the most important processes regulated by the signaling pathways discussed in earlier chapters.

22.1 Early Mammalian Development, Embryonic Stem Cells, and Induced Pluripotent Stem Cells

Fertilization Unifies the Genome

It is remarkable that a mammalian sperm is ever able to reach and insert its nucleus into an egg; in humans, each sperm is competing with more than 100 million others for a single oocyte. After the first sperm succeeds in fusing its membrane with the oocyte membrane, a flux of calcium flows into the oocyte cytosol, spreading outward from the site of sperm binding. As in other regulated secretory pathways, one of the effects of the rise in calcium is to trigger fusion of vesicles located just under the plasma membrane of the egg, called *cortical granules*, with the plasma membrane, releasing their contents to the outside of the plasma membrane and forming a shielding fertilization membrane that blocks other sperm from binding to the egg. Finally the sperm nucleus enters the egg cytoplasm, and the egg and sperm nuclei fuse to create the diploid zygote nucleus.

Oocytes contain multiple mitochondria, and in mammals and many other species inheritance of mitochondrial DNA is exclusively

maternal; little if any sperm mitochondrial DNA enters the oocyte (see Chapter 12). Female-specific mitochondrial DNA inheritance has been used to trace maternal heritage in human history, for example, to follow early humans from their origins in Africa. The egg cytoplasm is also packed with *maternal mRNA*: transcripts of genes whose products are essential for the earliest stages of development. There is little or no transcription during oocyte meiosis and the first embryonic cleavages, so during this time the oocyte's mRNA is crucial for protein production.

Cleavage of the Mammalian Embryo Leads to the First Differentiation Events

The fertilized egg, or zygote, does not remain a single cell for long. Fertilization is quickly followed by *cleavage*, a series of cell divisions that take about one day each (Figure 22-2); these divisions happen before the embryo is implanted in the uterine wall. Initially, the cells are fairly spherical and loosely attached to one another. As demonstrated experimentally, each cell at the eight-cell stage is totipotent and has the potential to give rise to a complete animal when implanted into the uterus of a pseudopregnant animal (one treated with hormones to make her uterus responsive to embryos). It is likely that each of the cells in eight-cell human and other mammalian embryos are also totipotent and that totipotency is lost

during later cleavages, though the timing may be different from that of a mouse embryo.

FIGURE 22-2 Early cleavage divisions in the mouse embryo. There is little cell growth during these early divisions, so the cells become progressively smaller. See text for discussion.

The eight-cell embryo undergoes compaction — a process that depends in part on induction of the cell-surface homotypic cell-adhesion protein E-cadherin (see Figure 20-14) that both causes substantial increases in the affinities of the blastomere cells for one another and polarizes the cells. Three days after fertilization, the eight-cell embryo divides to form the 16-cell *morula* (from the Greek for "raspberry"; see Figure 22-2); during this division one of the daughters of each blastomere ends up in an internal position of the 16-cell embryo whereas the other remains on the surface. The outer cells of the 16-cell embryo are fated to become the **trophectoderm (TE)** of the later 64-cell stage termed the **blastocyst** (see Figures 22-2 and 22-3) and will form extraembryonic tissues such as the placenta. The inner cells of the 16-cell embryo are fated to become the **inner cell mass (ICM)** of the blastocyst (just 10–15 cells in a mouse), which

gives rise to the embryo proper (Figure 22-3). During these divisions, fluid flows into an internal cavity called the *blastocoel*.

FIGURE 22-3 Schematic representation of mouse and human pre- and postimplantation embryos and the stem-cell lines that can be derived from them. In both mice and humans, a four-cell embryo normally develops into a blastocyst consisting of trophectoderm (TE) cells on the outside and inner cell mass (ICM) cells inside (see Figure 22-2); the ICM gives rise to cells that will form the extraembryonic primitive endoderm (PE) and the remaining cells differentiate into epiblast cells that will give rise to the embryo proper. After implantation into the wall of the uterus the detailed development of the mouse and human embryo differ, but in both cases the epiblast cells form the embryo proper; these cells and the earlier ICM cells can form embryonic stem cells when placed in culture. The extraembryonic cells form part of the placenta together with cells from the uterine wall. Extraembryonic tissues are shown in different shades of teal and epiblast derivatives in pink.

[Information from M. N. Shahbazi, E. D. Siggia, and M. Zernicka-Goetz, 2019, *Science* **364**:948.]

In the blastocyst, the ICM is found on one side of the blastocoel, while the TE cells form a hollow ball around the ICM and blastocoel. At this point, the TE cells are in an epithelial sheet, while the ICM cells are a loose mass that can be described as mesenchyme. *Mesenchyme*, a term most commonly applied to mesoderm-derived cells, refers to loosely organized and loosely attached cells. The fate of a cell in the early embryo — TE or ICM — is determined by the cell's location. If a labeled cell is placed on the outside of a very early embryo, it is likely to form extraembryonic tissues, while a cell placed inside an embryo is likely to form embryonic tissues. Both ICM and TE cells are stem cells: each starts its own distinct lineage and divides prolifically to produce diverse populations of cells. Gene expression measurements of each stage of early development show dramatic changes in which genes are expressed in ICM and TC cells and their descendants. Even these very early embryos use Wnt, Notch, and TGF-β signals to regulate gene expression (see Chapter 16).

Pluripotent Cells of the Inner Cell Mass Are the Source of ES Cells

ES cells can be isolated from the inner cell mass of early mammalian embryos and grown indefinitely in culture when attached to a feeder-cell layer that provides certain essential growth

factors (Figure 22-4a). As mentioned in the chapter introduction, cultured ES cells are pluripotent: they can differentiate into a wide range of cell types of the three primary germ layers, either in culture or after reinsertion into a host embryo. More specifically, mouse ES cells can be injected into the blastocoel of an early mouse embryo and the cell aggregate surgically transplanted into the uterus of a pseudopregnant female. The injected ES cells will participate in forming most, if not all, tissues of the resultant chimeric mice. Furthermore, the injected ES cells will often give rise to functional sperm and eggs that, in turn, can generate normal live mice.

EXPERIMENTAL FIGURE 22-4 ES cells can be maintained in culture and can form differentiated cell types. (a) Human or mouse blastocysts are grown from cleavage-stage embryos produced by in vitro fertilization. The ICM or the developmentally later epiblast (see Figure 22-3) is separated from the surrounding extraembryonic tissues and plated onto a layer of fibroblast cells, which help to nourish the embryonic cells by providing specific growth factors. When individual cells are replated, they form colonies of ES cells, which can be maintained for many generations and can be stored frozen. ES cells can also be cultured without a fibroblast feeder layer if specific cytokines are added; leukemia inhibitory factor (LIF), for instance, supports growth of mouse ES cells by triggering activation of the Stat3 transcription factor; see J. S. Odorico et al., 2001, *Stem Cells* **19**:193. (b) Embryonic stem cells allowed to differentiate in suspension culture form multicellular aggregates termed *embryoid bodies*. (c) Hematoxylin- and eosin-stained sections of embryoid bodies that contain derivatives of all three germ layers formed from the ICM during embryogenesis.

Arrows in the images point to the following tissue types: (*left*) gut epithelium (endoderm), (*middle*) cartilage (mesoderm), and (*right*) neuroepithelial rosettes (ectoderm). Black bar = 100 μm.

In a more recent variation on these experiments, a host zygote is treated with drugs that transiently block mitosis so that it and the blastocyst it forms are tetraploid (with four copies of each chromosome), incapable of forming differentiated cells and tissues. When normal diploid ES cells are injected into such a blastocyst, all the cells in the live mice that are born after transplantation of the blastocyst aggregate derive from the donor ES cells. This finding is powerful evidence that single mouse ES cells are indeed pluripotent. Because ethical considerations and, in many countries, legal restrictions preclude similar transplantation experiments with human ES cells, formal proof that human ES are pluripotent is lacking.

Importantly, both human and mouse ES cells can differentiate into a wide range of cell types in culture. When cultured in suspension, ES cells form multicellular aggregates, called *embryoid bodies* (Figure 22-4b), that resemble early embryos in the variety of tissues they form. When embryoid bodies are subsequently treated with various combinations of growth factors or transferred to a solid surface, they produce a variety of differentiated cell types, including gut epithelia, cartilage, and neural cells (Figure 22-4c). Under other conditions, ES cells have been induced to differentiate in culture into precursors for multiple specific cell types, including blood cells

and pigmented epithelia; for this reason, ES cells have proved extremely useful in identifying the factors that commit a pluripotent cell to differentiating down a particular cell lineage.

What properties give these cells of the early embryo their remarkable plasticity? As we will see in the next section, a variety of actors play a role: DNA methylation, transcription factors, chromatin regulators, and micro-RNAs all affect which genes become active.

Multiple Factors Control the Pluripotency of ES Cells

During the earliest stages of embryogenesis, as the zygote begins to divide, both the paternal and maternal DNA become demethylated (see the discussion of DNA methylation in Chapter 8). This happens in part because a key maintenance methyl transferase, Dnmt1, is transiently excluded from the nucleus and in part because demethylase enzymes actively remove (or "erase") methylation marks from 5-methyl cytosine residues during early development. As a result, the pattern of DNA methylation is reset during the first few cell divisions, erasing earlier epigenetic marking of the DNA and creating conditions in which cells have greater potential for diverse pathways of development. Mice engineered to lack Dnmt1 die as early embryos with drastically undermethylated DNA. ES cells

prepared from such embryos are able to divide in culture, but in contrast to normal ES cells, cannot undergo in vitro differentiation.

ES cell properties are also critically dependent on the action of master transcription factors produced shortly after fertilization. The transcription factors Oct4, Sox2, and Nanog have essential roles in early development and are required for the specification of ICM cells in the embryo as well as for the specification of ES cells in culture. The expression of Oct4 and Nanog is exclusive to pluripotent cells such as the cells of the ICM and cultured ES cells. Sox2 is expressed in pluripotent cells, but its expression is also necessary in the multipotent neural stem cells that give rise exclusively to neuronal and glial cell types (discussed in Chapter 23). Genetic studies in mice suggest that these three regulators have distinct roles but function in related pathways to maintain the developmental potential of pluripotent cells. For example, disruption of Oct4 or Sox2 results in the inappropriate differentiation of ICM and ES cells into trophectoderm. Thus knowledge of the set of genes regulated by these transcription factors might reveal their essential roles during development.

The genes that are bound by these three transcription factors have been identified using chromatin immunoprecipitation experiments (see Chapter 8); each protein is found at more than a thousand chromosomal locations. The target genes encode a wide variety of proteins, including the Oct4, Nanog, and Sox2 proteins themselves, forming an autoregulatory loop in which each of these three

transcription factors induces its own expression as well as that of the others (Figure 22-5). These transcription factors also bind to the transcription-control regions of many genes encoding proteins and micro-RNAs important for the proliferation and self-renewal of ES cells.

FIGURE 22-5 Basic transcriptional network regulating pluripotency of ES cells. The master transcription factors Oct4 and Sox2 form a dimer, and each of the three transcription factors, Oct4, Sox2, and Nanog, binds to its own promoter as well as to the promoters of the other two (black lines), forming a positive autoregulatory loop that activates transcription of each of these three genes. These transcription factors also bind to the transcription-control regions of many active genes encoding proteins and micro-RNAs important for the proliferation and self-renewal of ES cells as well as to those of many genes that are silenced in undifferentiated ES cells and that encode proteins and micro-RNAs essential for the formation of many differentiated cell types (magenta lines). See M. Li and J. C. Izpisua Belmonte, 2018, *Nat. Cell Biol.* **20**:382.

Several protein hormones are provided by feeder cells or added to culture media to prevent differentiation of ES cells. These hormones

include leukemia inhibitory factor (LIF), which activates Stat3; Wnt, which activates the β-catenin transcription factor; and bone morphogenetic protein 4 (BMP4), which activates the Smad1 transcription factor (see Chapter 16). In ES cells, these three transcription factors bind at multiple genomic sites co-occupied by Oct4, Nanog, and Sox2 proteins. Thus signaling pathways activated by cell-surface receptors are directly coupled to regulation of genes in the core pluripotency circuitry; this observation reinforces a point made in Chapter 16 that transcription factors activated by cell-surface receptors frequently bind at sites in the genome occupied by master transcription factors specific to that type of cell.

Chromatin regulators that control gene transcription (see Chapter 8) are also important in ES cells. In *Drosophila*, Polycomb group proteins form complexes to maintain gene repression states that have been previously established by DNA-binding transcription factors. Two mammalian protein complexes related to the fly Polycomb proteins, PRC1 and PRC2 (see Figure 8-48), are abundant in ES cells. Early mouse embryos lacking components of PRC2 display early developmental defects. The PRC2 complex acts by adding methyl groups to lysine 27 of histone H3, thus altering chromatin structure to repress genes. (Note that the methylation here is on an amino acid in a protein, a type of regulation distinct from the methylation of cytosine residues in DNA.) In ES cells, PRC1 and PRC2 both silence genes whose encoded proteins or micro-RNAs (miRNAs) would otherwise induce differentiation into

particular types of cells; the Polycomb proteins also maintain these genes in an epigenetic preactivation state such that they are poised to become activated later as part of the proper execution of specific developmental gene expression programs. Thus ES cells lacking PRC2 functions fail to differentiate properly.

Many other regulators play important roles in controlling gene expression and maintaining pluripotency during very early development. For example, the gene encoding the miRNA *let-7* is transcribed in ES cells, but the precursor RNA transcript is not cleaved to form the mature, functional miRNA. ES cells express a developmentally regulated RNA-binding protein termed *Lin28* that binds to the *let-7* precursor RNA and prevents its cleavage. *Let-7* is essential for differentiation of ES cells, and experimental expression of mature *let-7* miRNA in ES cells blocks their ability to undergo self-renewal. Thus repression of *let-7* processing by Lin28 is essential for pluripotency.

As we will see later in this section, the possibility of using embryonic stem cells therapeutically to restore or replace damaged tissue is fueling much research on how to induce them to differentiate into specific cell types. Apart from their possible benefit in treating disease, ES cells have already proved invaluable for producing mouse mutants useful in studying a wide range of diseases, developmental mechanisms, behavior, and physiology. Using the recombinant DNA techniques described in Chapter 6, one

can eliminate or modify the function of a specific gene in ES cells. The mutated ES cells can then be employed to produce mice with a gene knockout or modification (see Figure 6-40). Analysis of the effects of deleting or modifying a gene in this way often provides clues about the normal function of the gene and its encoded protein.

Animal Cloning Shows That Epigenetic Changes During Differentiation Can Be Reversed

Although different cell types may transcribe different parts of the genome, for the most part the genome is identical in all cells. Segments of the genome are rearranged and lost during development of the T and B lymphocytes of the immune system from hematopoietic precursors (see Chapter 24), but most somatic cells appear to have an intact genome, equivalent to that in the germ line. Evidence that at least some somatic cells have a complete and functional genome comes from the successful production of cloned animals by nuclear transfer. In this procedure, often called *somatic-cell nuclear transfer* (SCNT), the nucleus of an adult somatic cell is introduced into an egg whose nucleus has been removed; the manipulated egg, which contains the diploid number of chromosomes and is equivalent to a zygote, is then implanted into a foster mother. Outside of the few genes in mitochondrial DNAs that remain in the egg, the only source of genetic information to guide

development of the embryo is the nuclear genome of the donor somatic cell. The low efficiency of generating cloned animals by SCNT, combined with a high frequency of diseases such as obesity in the animals that are cloned, however, raises questions about how many adult somatic cells do in fact have a complete functional genome and whether those that do can be completely reprogrammed into a pluripotent undifferentiated state. Even the successes, such as the famous cloned sheep "Dolly," have some medical problems. If differentiated cells do have a physically complete genome, clearly only parts of it are transcriptionally active (see Chapter 8). A cell could, for example, have an intact genome, but be unable to properly reactivate specific genes due to inherited chromatin epigenetic states.

Further evidence that the genome of a differentiated cell can revert to having the full developmental potential characteristic of an ES cell comes from experiments in which olfactory sensory neurons — postmitotic cells that normally will not divide again — were genetically marked with green fluorescence protein (GFP) and then used as donors of nuclei (Figure 22-6). When the nuclei from differentiated olfactory sensory neurons were implanted into enucleated mouse oocytes, a small fraction of them developed into blastocysts that produced GFP. The blastocysts were used to derive ES cell lines, which were then injected into tetraploid blastocysts. These manipulated embryos, derived entirely from olfactory sensory neuron genomes, formed healthy mice in which all cells expressed the GFP. Thus, at least in some cases, the genome of a

terminally differentiated cell can be reprogrammed completely to form all tissues of a mouse.

EXPERIMENTAL FIGURE 22-6 Mice can be cloned by somatic-cell nuclear transfer from olfactory neurons. (a) Procedure for generating cloned ES cell lines using nuclei from olfactory sensory neurons and using them to generate cloned mice. Step **1**: A nucleus from an olfactory sensory neuron isolated from a mouse that expresses green fluorescent protein (GFP) only in its olfactory neurons was used to replace the nucleus of a mouse egg. Step **2**: The resultant zygote was cultured to the blastocyst stage. Step **3**: The ICM cells, all of which were clones of the original olfactory sensory neuron, and all of which expressed GFP, were used to generate lines of ES cells. Step **4**: These ES cells were injected into a tetraploid blastocyst. Step **5**: When the blastocyst was transplanted into the uterus of a pseudopregnant mouse, the tetraploid cells from the host blastocyst could form the placenta (violet), but not the embryo proper. Step **6**: Therefore, all of cells in the embryo proper and in the mouse that developed from it expressed GFP. (b–c) Bright-field (*top*) and fluorescence images (*bottom*) of (b) nuclear-transfer blastocysts and (c) the ES cells that were isolated from the ICM. (d) A control 12-hour-old mouse (*top*) and a mouse cloned from an olfactory sensory neuron, all of whose cells expressed GFP (*bottom*).

Somatic Cells Can Generate iPS Cells

Because of the inefficiency of SCNT, it remained unclear whether all types of somatic mammalian cells retained an intact genome and whether they could be induced to dedifferentiate into an ES cell–like state. Shinya Yamanaka, who won the 2012 Nobel Prize for this research, used retrovirus vectors to express a wide variety of transcription factors, singly and in combination, in cultured fibroblast cells. Remarkably, he found that both human and mouse fibroblasts could be reprogrammed to a pluripotent state, called an *induced pluripotent stem-cell state*, similar to that of an ES cell, by transformation with retroviruses encoding just four proteins: KLF4, Sox2, Oct4, and Myc. Note that two of these, Sox2 and Oct4, are two of the master transcription factors expressed in ES cells, as discussed previously. In addition to fibroblasts, keratinocytes (skin-forming cells) and other types of differentiated cells have been reprogrammed to iPS cells. Like ES cells, single mouse iPS cells can be experimentally introduced into a blastocyst and form all of the tissues of a mouse, including germ cells, attesting to the fact that somatic cells can indeed be reprogrammed to an embryonic pluripotent state.

Several other transcription factors, and even certain small organic molecules, can replace the Oct4 gene in the Yamanaka reprogramming cocktail. Subsequent analysis led to the discovery that each of these factors directly activates transcription of the endogenous (cellular) Oct4 gene, leading to induction of pluripotency. Thus it was hypothesized that, over time, forced expression of transcription-factor genes activates expression of many cellular genes, including those encoding Oct4 and other pluripotency proteins; over the course of several weeks, this activation reprograms at least some of the somatic cells to an ES-like state. To experimentally establish the point that activation of endogenous genes leads to reprogramming to an ES-like state, cultured keratinocytes were repeatedly transfected with synthetic mRNAs encoding the four canonical Yamanaka transcription factors, KLF4, Sox2, Oct4, and Myc. These cultured cells generated normal iPS cells that had no trace of any of the exogenously added mRNAs, attesting to the reprogramming of keratinocytes into iPS cells by inducing expression of only normal cellular genes.

In fibroblasts, the chromatin of most pluripotency-associated genes is inaccessible to transcription-factor binding, primarily due to the repressive histone H3 lysine 9 trimethylation ($H3K9Me_3$) mark. Among the genes activated by Oct4 are two that encode H3K9 demethylases, which remove these repressive chromatin marks and, over time, result in activation of pluripotency genes. Consistent with this notion, expression of these H3K9 demethylases increases during reprogramming, and their knockdown inhibits efficient iPS-

cell generation. Indeed, reprogramming involves other major changes in epigenetic modifications as well, including DNA methylation and several other types of histone modifications that serve to repress or allow potential activation of hundreds of genes.

Among the genes up-regulated during reprogramming is LIN28. As discussed above, LIN28 promotes pluripotency by blocking biogenesis of members of the *let-7* family of micro-RNAs. Expression of telomerase (see Figure 7-40) is also induced during reprogramming; telomerase restores the normal length of telomeres that are shortened during the many rounds of cell divisions required for certain types of differentiated cells to form. Cellular reprogramming to pluripotency is also accompanied by a rewiring of metabolic pathways: a metabolic shift from a highly respiratory metabolism characteristic of most types of differentiated cells, which depend on mitochondria for ATP production, to a highly glycolytic carbon flux characteristic of ICM cells in a normal embryo.

Patient-Specific iPS Cells Can Be Used to Develop Potential Treatments for Many Diseases

Because iPS cells can be derived from somatic cells of patients with difficult-to-understand diseases, they have already proved

invaluable in uncovering the molecular and cellular basis of several afflictions (Figure 22-7). Consider *amyotrophic lateral sclerosis (ALS)*, often called *Lou Gehrig's disease*, a fatal disease in which the motor neurons that connect the spinal cord to the muscles of the body progressively die off, causing muscle weakness and death, limb paralysis, and ultimately death due to respiratory failure. There is no cure.

FIGURE 22-7 Medical applications of iPS cells. In this example, the patient has a neurodegenerative disorder caused by abnormalities in certain nerve cells (neurons).

Patient-specific iPS cells — in this case derived by recombinant expression of the four Yamanaka transcription factors in cells isolated from a skin biopsy — can be used in one of two ways. In cases in which the disease-causing mutation is known (e.g., familial Parkinson's disease), gene targeting could be used to repair the DNA sequence (*right*). The gene-corrected patient-specific iPS cells would then undergo directed differentiation into the affected neuronal subtype (e.g., midbrain dopaminergic neurons) and be transplanted into the patient's brain (to engraft the nigrostriatal axis). Alternatively, directed differentiation of the patient-specific iPS cells into the affected neuronal subtype (*left*) will allow the patient's disease to be modeled in vitro, and potential drugs can be screened, aiding in the discovery of novel therapeutic compounds.

[Information from D. A. Robinton and G. Q. Daley, 2012, *Nature* **481**:295.]

In approximately 10 percent of patients, the disease is dominantly inherited (familial ALS), but in 90 percent of patients, there is no apparent genetic linkage (sporadic ALS). An analysis of the underlying causes of the disease at a molecular and cellular level was impossible for many years because one cannot simply extract neurons or the surrounding glial cells (see Chapter 23) to analyze or culture from living humans. In several studies, iPS cells derived from the skin cells of elderly patients with these and other familial and sporadic forms of the disease were successfully differentiated in culture to form motor neurons; this success demonstrated the feasibility of leveraging the self-renewal of iPS cells to generate a potentially limitless supply of the cells specifically affected by ALS. Early studies showed that motor neurons bearing several types of ALS mutations were hyperexcitable, generating more of the electrical signals called *action potentials* (see Chapter 23) than normal. Using these differentiated neurons, researchers screened

thousands of small organic molecules, including many approved as drugs for treatment of other unrelated diseases, for those that could reverse the abnormalities in the ALS iPS cell–derived motor neurons. Several were identified and are in clinical trials to see if they can slow or stop the devastating effects of ALS. These experiments illustrate the value of iPS and ES cells in generating cell culture models of many types of difficult-to-study human diseases that can be used to screen for drugs that could treat many as yet untreatable afflictions. ■

ES and iPS Cells Can Generate Functional Differentiated Human Cells

Neurons and glial cells, as well as other cell types derived from human iPS cells have been implanted into mice with some promising results. Specifically, mouse stem cell–derived cardiomyocytes (heart muscle cells) can correct heart arrhythmias in mice; certain glial cells — oligodendrocytes — show promise in aiding recovery from experimental spinal injury in mice; and retinal epithelial cells can partially correct defects in mouse models of blindness. It is not yet known whether similar differentiated cells derived from human iPS cells can function when transplanted into humans.

One recent advance — the generation of normal insulin-secreting β islet cells from human iPS and ES cells — shows promise for treatment of both type 1 and type 2 diabetes. Type 1 diabetes results from autoimmune destruction of pancreatic β cells, whereas the more common type 2 diabetes results from insulin resistance in liver and muscle (see Figures 21-1 and 21-2), eventually leading to dysfunction and death of β cells. Patients who receive transplants of human islets from cadavers can be made insulin independent for 5 years or longer, but this approach is limited because of the scarcity and quality of donor islets; the possibility of an unlimited supply of human β cells from stem cells could potentially extend this therapy to millions of new patients.

One key to this successful generation of β cells was employing successive treatment with different combinations of growth factors that stimulated iPS or ES cells to traverse the multiple steps of the normal embryonic developmental sequence by which the progeny of undifferentiated ICM cells form mature functional β cells (Figure 22-8a). The so-called *SC-β cells* that resulted have a structure very similar to that of normal β islet cells, including secretory granules filled with almost crystalline insulin; they also secrete normal amounts of insulin in response to elevation of the glucose level in their culture medium. Shortly after their transplantation into mice, these cells secrete human insulin into the blood in a glucose-regulated manner. Most important, after transplantation of these cells into immunocompromised diabetic mice, their high glucose

levels are lowered to normal (Figure 22-8b), indicating the potential use of these β islet cells — which can be produced in culture in essentially unlimited numbers — for the treatment of diabetes. Screening to identify new drugs that improve β cell function, survival, or proliferation can also make use of such a uniform supply of stem cell–derived β cells. As detailed in Chapter 21 (Figure 21-1), normal islets also contain α cells that secrete glucagon as well as other cell types; one goal is to generate from iPS cells islet-like cell aggregates that contain both α and β cells.

FIGURE 22-8 Production of normal insulin-secreting β islet cells from human iPS or ES cells. (a) Schematic of directed differentiation of human ES or iPS cells into insulin-secreting β islet cells. Clusters of a few hundred human ES or iPS cells were sequentially cultured in

media containing the indicated growth factors for the indicated number of days to first produce definitive endoderm cells, then a series of embryonic pancreatic progenitor cells, then pancreatic endocrine progenitors, and finally stem cell–derived insulin-producing β islet cells (termed *SC-β cells*). Abbreviations indicate the multiple signaling molecules that are employed: Act A, activin A; CHIR, GSK3 inhibitor; KGF, keratinocyte growth factor; RA, retinoic acid; SANT1, Sonic Hedgehog pathway antagonist; LDN, a BMP type 1 receptor inhibitor; PdbU, a protein kinase C activator; Alk5i, Alk5 receptor inhibitor II; T3, triiodothyronine, a thyroid hormone; XXI, γ-secretase inhibitor; betacellulin, an EGF family member. (b) These experiments used a strain of diabetic mice with a mutation in the insulin gene as well as in several immune-system genes such that the animals did not reject transplants of human tissue. Previous work had shown that the elevated glucose levels in these mice could be restored to normal by transplantation with human pancreatic islets. In this experiment, mice were transplanted with SC-β cells (black circles) or a similar number of control pancreatic progenitor cells (white circles). At the start of the experiment, the average blood glucose level in these mice was about 11 mM, well above the normal 5 mM. The average blood glucose level in the control mice rose continuously to about 30 mM, indicating severe diabetes, while in the mice transplanted with the human SC-β cells, blood glucose dropped to nearly the normal 5 mM.

[Part (b) Data from F. W. Pagliuca et al., 2014, *Cell* **159**:428.]

The coming years are certain to see the development of many other types of differentiated cells from human iPS cells that can be used as replacement parts for a variety of maladies. Indeed, fully functional mouse oocytes have been generated in culture from mouse ES cells and also from induced pluripotent stem cells derived from both embryonic fibroblasts and adult tail tip fibroblasts (Figure 22-9). When subjected to in vitro fertilization with wild-type sperm, all of these in vitro–generated oocytes developed to two-cell embryos. Remarkably, several of these two-cell embryos transferred

to pseudopregnant females were successfully delivered as viable pups.

FIGURE 22-9 Production of functional mouse oocytes from pluripotent stem cells. (a) A schematic of oocyte production in vitro. Female mouse ES cells were first differentiated in culture to form primordial germ cell-like cells (PGCLCs) and then cultured together with female gonadal somatic cells isolated from a Day 12.5 mouse embryo to form primitive ovary-like aggregates. After 2–3 weeks in culture, primary oocytes had formed in which the

developing oocytes were surrounded by stromal cells; many oocyte progenitors were undergoing meiosis. After further culture, mature haploid oocytes — metaphase II (MII) — had formed. (b) After the final MII stage of differentiation, in vitro–generated oocytes were subjected to in vitro fertilization with wild-type sperm; all of these in vitro–generated oocytes were fertilized and developed to two-cell embryos. Note the polar bodies, small haploid cells that are the other products of meiosis and do not have the ability to be fertilized.

[Part (b) republished with permission from Springer Nature, from O. Hikabe et al., 2016, "Reconstitution In Vitro of the Entire Cycle of the Mouse Female Germ Line," *Nature* **539**:299–303; permission conveyed through Copyright Clearance Center, Inc.]

Many important questions must be answered, however, before the feasibility of using differentiated cells or eggs derived from human ES or iPS cells for therapeutic purposes can be assessed adequately. For instance, when undifferentiated human or mouse ES or iPS cells are transplanted into an experimental mouse, they form teratomas, tumors that contains masses of partially differentiated cell types. Thus it is essential to ensure that all of the ES or iPS cells used to generate an implant have indeed undergone differentiation and have lost their pluripotency and their ability to induce teratomas or cause other problems. Many groups are trying to generate fully functional oocytes from human ES or iPS cells as a treatment for certain types of female infertility. With the prospect of making babies from in vitro–derived oocytes on the horizon, combined with the possibility of editing the genomes of the ES cells that give rise to these oocytes, it is incumbent on society at large to grapple with the complex ethical issues at stake. Scientists and nonscientists alike should prioritize and expedite these debates.

KEY CONCEPTS OF SECTION 22.1

Early Mammalian Development, Embryonic Stem Cells, and Induced Pluripotent Stem Cells

- In asymmetric cell division, two different types of daughter cells are formed from one parent cell. In contrast, both daughter cells formed in symmetric cell divisions are identical but may have different fates if they are exposed to different external signals (see Figure 22-1).
- Fusion of a haploid sperm and haploid egg nucleus generates a diploid zygote. The initial divisions of the mammalian embryo yield equivalent totipotent cells (see Figure 22-2), but subsequent divisions yield the first differentiation event, the separation of the trophectoderm from the inner cell mass (see Figure 22-3).
- The inner cell mass is the source of the embryo proper as well as of embryonic stem cells (ES cells).
- Cultured ES cells are pluripotent, capable of giving rise to all differentiated cell types of the organism with the exception of extraembryonic tissues. They are useful in the production of genetically altered mice and offer the potential for therapeutic uses.
- The pluripotency of ES cells is controlled by multiple factors, including the state of DNA methylation, chromatin regulators, certain micro-RNAs, and the transcription factors Oct4, Sox2, and Nanog.
- Animal cloning establishes that cell differentiation can be reversed.
- Induced pluripotent stem (iPS) cells can be formed from somatic cells by expression of combinations of key transcription factors, including KLF4, Sox2, Oct4, and Myc.
- As exemplified by ALS, differentiated cells produced in culture from human iPS cells can be used to understand the underlying cause of a disease as well as to screen drugs that could be used to treat the disease.
- β islet cells produced in culture from human iPS cells secrete insulin normally in response to an elevation of glucose in the media and reverse the high glucose levels in diabetic mice.
- Fully functional mouse oocytes can be produced in culture from mouse ES and iPS cells.

22.2 Stem Cells and Niches in Multicellular Organisms

Many types of differentiated cells are sloughed from the body or have life spans that are shorter than that of the organism. Disease and trauma can also lead to losses of differentiated cells. Since most types of differentiated cells do not divide, they must be replenished from nearby somatic stem-cell populations. In vertebrates and most invertebrates, such stem cells, in contrast to pluripotent ES cells, are *unipotent* or multipotent in that they can give rise to one or several, but not all, of the cell types found in the organism. Postnatal (adult) vertebrate animals contain stem cells for many tissues, including the blood, intestines, skin, ovaries, testes, and muscle. Even some parts of the adult brain, where little cell division occurs, have populations of neuronal stem cells (see Chapter 23). In striated muscle, stem cells are most important in healing, as relatively little cell division occurs at other times. Some other cell types, such as liver cells (hepatocytes) and insulin-producing β islet cells, reproduce mainly by division of already differentiated cells, as exemplified by regeneration of the liver when large pieces are surgically removed.

Adult Planarians Contain Pluripotent Stem Cells

We noted in Chapters 1 and 16 that small body segments of planaria can regenerate whole animals. Regeneration was known to require a population of proliferating stem cell–like cells, termed **neoblasts**, that are present throughout the adult body, but a key question was whether regeneration is accomplished, as in many animals with this capability, by the collective activity of multiple lineage-restricted stem or progenitor cells, or whether pluripotent stem cells are involved. Recent experiments showed that adult planarians contain lineage-restricted neoblasts as well as pluripotent stem cells, termed *clonogenic neoblasts*, or *cNeoblasts*.

The key studies used gamma irradiation to inhibit most or all cell division in adult planarians; the treated animals could not regenerate and suffered massive tissue loss because of failed replacement of aged, differentiated cells. The few functional proliferating neoblast cells remaining after irradiation could be identified by a marker gene termed *smedwi-1*. Several days after irradiation, individual neoblasts formed colonies of *smedwi-1*-positive cells that contained multiple types of differentiated body cells, and it was hypothesized that this *smedwi-1*-positive subpopulation of neoblasts was pluripotent (Figure 22-10). To test this hypothesis, single neoblasts were transplanted into lethally irradiated planaria that lacked all of their own neoblasts. Remarkably, several transplant recipients lived past 7 weeks and regenerated, from the single transplanted cell, neuronal, intestinal, and other differentiated cell types that were distributed throughout

the body. The animals eventually regained feeding behavior and regenerated complex tissues, including eyes. These experiments indicated that at least some of the neoblast stem cells in adult planarians are indeed pluripotent, providing a cellular basis for the remarkable regenerative abilities of planarians. Despite much effort, no pluripotent stem cells have ever been reliably identified in any adult vertebrate organism.

EXPERIMENTAL FIGURE 22-10 Broad differentiation potential of individual neoblasts in planarians. Planarians were subjected to subtotal irradiation, which leaves few surviving neoblasts, but one surviving neoblast grew into a colony of neoblasts in the head. (a) Neoblasts are labeled in green with an antibody to the SMEDWI-1 protein. The *smedwi-1* gene is specifically transcribed in neoblasts, and transcription stops when a neoblast progeny cell stops dividing and differentiates. The SMEDWI-1 protein produced in neoblasts slowly degrades during differentiation into mature cell types, but enough remains to detect the progeny of this neoblast. (b) Double-labeling with the SMEDWI-1 antibody and fluorescent in situ hybridization with RNA probes for markers for differentiated cells therefore detects newly produced differentiated cells derived from the single neoblast. Neurons are labeled in magenta with an RNA probe to the gene *chat* and intestine cells are labeled in blue with an RNA

probe to the gene *gata4/5/6*. Anterior is up. See D. E. Wagner, I. E. Wang, and P. W. Reddien, 2011, *Science* **332**:811.

Multipotent Somatic Stem Cells Give Rise to Both Stem Cells and Differentiating Cells

The most common type of stem cells in adult metazoans, multipotent somatic stem cells, give rise to the specialized cells composing body tissues. The two critical properties of these stem cells that together distinguish them from all other cells are the ability to reproduce themselves during many cell divisions (self-renewal) and the ability to generate progeny of more restricted potential. Multipotent somatic stem cells have two other key properties (Figure 22-11):

1. They can give rise to multiple types of differentiated cells. In this sense, they differ from **progenitor cells** (also called *precursor cells*), which generally give rise to only one or two types of differentiated cells. A stem cell has the capability of generating a number of different cell types, but not all cell types: it is not pluripotent like an ES cell. For instance, a multipotent hematopoietic (blood) stem cell will form more of itself plus multiple types of blood and immune cells, but never a skin or a liver cell.

2. They are stem cells in that they are undifferentiated; in general, they do not express mRNAs or proteins characteristic of the differentiated cell types formed by their descendants. Stem cells of a particular type generally appear during embryonic development and rapidly increase in number; their progeny produce the many types of differentiated cells that make up the embryo and juvenile. Once adulthood is reached, the number of stem cells remains relatively constant and often declines with age. In that sense, stem cells are often said to be immortal, although no single stem cell survives for the life of the animal. Indeed, when pushed to divide more frequently than normal by chronic tissue injury, repeated rounds of chemotherapy, or genetic defects that impair genomic integrity, stem cells consistently exhibit a finite replicative capacity.

FIGURE 22-11 The pathway from stem cells to lineage-restricted progenitors to differentiated cells. On average, during each division of a multipotent somatic stem cell, at least one of the daughter cells becomes a stem cell like the parent cell. Stem cells thus undergo self-renewal divisions such that the number of stem cells of a particular type can stay constant during the organism's lifetime. Other daughter cells, termed *transit amplifying cells*, divide rapidly and can undergo limited numbers of self-renewal divisions in which the properties of the daughter cells closely resemble those of the parent. These cells ultimately produce lineage-restricted progenitor cells, which cannot undergo self-renewal divisions but can divide and produce differentiated cells of a particular type.

Many types of stem cells in the adult body divide infrequently; they are kept in reserve in case certain types of differentiated cells are required. In contrast, their non-stem-cell daughters frequently undergo many rapid rounds of cell division. Such cells, often called *transit amplifying cells* (see Figure 22-11), can undergo limited numbers of self-renewal divisions, but eventually their many progeny form lineage-restricted progenitor cells. These cells, in turn, can divide and generate very specific types of terminally differentiated cells.

Stem cells can exhibit several patterns of cell division. Some types of stem cells always divide asymmetrically to generate one copy of the parent cell and one daughter cell with more restricted capabilities, such as dividing for a limited time or giving rise to fewer types of progeny than the parent stem cell (Figure 22-12a). This type of stem-cell division is commonly found in invertebrates such as *Drosophila*, discussed below.

FIGURE 22-12 Patterns of stem-cell differentiation. Different patterns of stem-cell division produce different proportions of stem cells (red) and differentiating cells (green). (a) Stem cells can undergo asymmetric divisions, producing one stem cell and one differentiating cell. This pattern maintains the number of stem cells in the population. (b) Some stem cells can divide symmetrically to increase their numbers, which is often important in normal development or during recovery from injury. At the same time other stem cells in the same population can be dividing asymmetrically as in (a). (c) Some stem cells may divide as in (b) while at the same time other stem cells produce two differentiating progeny. See S. J. Morrison and J. Kimble, 2006, *Nature* **441**:1068–1074.

Other patterns of stem-cell division, commonly found in vertebrates, allow the number of stem cells or differentiated cells to increase or decrease according to the needs of the animal (Figure 22-12b, c). Hormones secreted by or on the surface of adjacent cells frequently regulate these patterns of stem-cell division. For example, a stem cell may divide symmetrically to yield two daughters that undergo different fates: depending on external signals sent by other cells, one may remain a stem cell and the other may become a transit amplifying cell that will undergo several

rounds of cell division and ultimately generate one or more types of differentiated progeny. As we will see in greater detail shortly, this happens in the small intestine: often one of the daughters remains a stem cell identical to its parent while the other daughter divides rapidly and generates multiple types of differentiated intestinal cells. Other stem-cell divisions are symmetric, producing two stem cells and increasing the number of stem cells of a particular type; this pattern of stem-cell division is common during development. Thus mitotic divisions of stem cells can either enlarge the population of stem cells or maintain a stem-cell population while steadily producing a stream of differentiating cells.

Stem Cells for Different Tissues Occupy Sustaining Niches

Stem cells need the right microenvironment to remain multipotent and to regulate the timing and pattern of their divisions. In addition to *intrinsic* regulatory signals — such as the presence of certain transcription factors and other regulatory proteins — stem cells rely on *extrinsic* hormonal and other signals from surrounding cells to maintain their status as stem cells. The location where a stem-cell fate can be maintained is called a **stem-cell niche**, by analogy to an ecological niche — a location that supports the existence and competitive advantage of a particular organism.

In order to investigate or use stem cells, we must find them and characterize them. It is often difficult to identify stem cells precisely; they are very rare among cells and generally lack distinctive shapes. Some stem cells divide rarely, if at all, until stimulated by signals that convey the need for new cells. For example, inadequate oxygen supplies can stimulate blood stem cells to divide, and injury to the skin or muscle can stimulate regenerative cell division starting with the activation of skin or muscle stem cells. Some stem cells, including those that form the continuously shed epithelium of the intestine, are continuously dividing, usually at a slow rate. In the rest of this section, we focus on several types of stem cells in plants and animals that are well characterized; in the coming years, undoubtedly other types of stem cells will also be understood in great detail.

Germ-Line Stem Cells in Many Organisms Produce Sperm or Oocytes

The **germ line** is the cell lineage that produces oocytes and sperm; it is distinct from the somatic cells that make all the other tissues but are not passed on to progeny. The germ line, like somatic-cell lineages, starts with stem cells, but these cells are unipotent in that they make only germ cells. Stem-cell niches have been especially well defined in studies of germ-line stem cells in *Drosophila* and *C.*

elegans. Germ-line stem cells are present in adult flies and worms, and the locations of these stem cells are well known.

In the fly, the niche where oocyte precursors form and begin to differentiate is located next to the tip of the *germarium*, the part of the ovary where eggs are formed (Figure 22-13a). There are two or three germ-line stem cells in this location next to a few cap cells, which create the niche by secreting two proteins in the TGF-β family, Dpp and Gbb, as well as Hedgehog (Hh) protein (Figure 22-13b). (These secreted protein signals were introduced in Chapter 16.) The cap cells create the niche because the TGF-β-class signals they send repress transcription of a key differentiation factor, the *Bag of marbles (Bam)* protein, in the neighboring germ-line stem cells. Repression of the *bam* gene allows germ-line stem cells to undergo self-renewing divisions, whereas activation of *bam* promotes differentiation. When a germ-line stem cell divides, one of the resulting daughters remains adjacent to the cap cells and is therefore maintained as a stem cell, like the parent cell. The other daughter is too far from the cap cells to receive the cap-cell-derived signals Dpp and Gbb. As a result, expression of the *bam* gene is induced, causing that daughter cell to enter the differentiation program. The signals involved were identified in part through the power of *Drosophila* genetics: mutant germ-line stem cells with defects in their Dpp or Gbb receptors, or their downstream signal transduction proteins, are lost prematurely. Conversely,

overexpression of Dpp by cap cells prevents differentiation of germ-line stem cells and causes formation of tumorlike germ cell masses.

FIGURE 22-13 A *Drosophila* germarium. (a) Cross section of the germarium, showing female germ-line stem cells (yellow) and some somatic stem cells (orange) in their niches and the progeny cells derived from them. The germ-line stem cells produce cystoblasts (dark purple), which undergo four rounds of mitotic division to produce 16 interconnected cystocyte cells (light purple), one of which becomes the oocyte; the somatic stem cells produce follicle cells

(brown), which will make the eggshell. The cap cells (dark green) create and maintain the niche for germ-line stem cells, while the inner sheath cells (blue) produce the niche for somatic stem cells. (b) Signaling pathways that control the properties of germ-line stem cells. The signaling molecules — the TGF-β-family proteins Dpp and Gbb as well as Hedgehog (Hh) — are secreted by the cap cells. Binding of these ligands to receptors on the surface of a germ-line stem cell — the TGF-β receptors I and II and Ptc, respectively — results in repression of the *bam* gene by two transcription factors, Mad and Med. Repression of *bam* allows germ-line stem cells to undergo self-renewal divisions, whereas activation of *bam* promotes differentiation. The transmembrane cell-adhesion protein E-cadherin forms the homotypic adherens junctions (Chapter 20) between germ-line stem cells and cap cells. Arm (Armadillo), the fly β-catenin, connects the cytoplasmic tails of the E-cadherin to the actin cytoskeleton; both E-cadherin and Arm are important in maintaining the stem cells in their niche. (c) Signaling pathways that control the properties of somatic stem cells. The Wnt signal Wingless (Wg) is secreted by the inner sheath cells and binds to the Frizzled receptor (Fz) on a somatic stem cell. Hh is similarly produced and binds to the Ptc receptor. Both of these signals result in self-renewal of somatic stem cells. See R. Lehmann, 2012, *Cell Stem Cell* **10**:729, https://doi.org/10.1016/j.stem.2012.05.016; and E. W. Kahney, J. C. Snedeker, and X. Chen, 2019, *Curr. Opin. Cell Biol.* **60**:27.

The stem cells are held in the niche by the transmembrane cell-surface protein E-cadherin (see Chapter 20), which forms adherens junctions via homotypic interactions with similar E-cadherin molecules on the cap cell. These adherens junctions orient the mitotic spindle of the germ-line stem cells such that one daughter remains attached to the cap cell and the other is displaced from the niche; similar asymmetric stem-cell divisions occur during other developmental stages in *Drosophila*, as we discuss later (see Figure 22-31b). *Armadillo (Arm)*, the fly β-catenin, connects the cytoplasmic

tails of the E-cadherin molecules to the actin cytoskeleton; like E-cadherin, Arm is important in maintaining the stem-cell niche.

Separate somatic stem cells in the germarium produce follicle cells that will make the eggshell. The somatic stem cells have a niche too, created by the inner sheath cells, which produce Wingless (Wg) protein — a fly Wnt signal — and Hh protein (Figure 22-13c). Thus two different populations of stem cells can work in close coordination to produce different parts of an egg.

The identification and characterization of *Drosophila* germ-line stem cells, as well as similar cells from *C. elegans*, were important because they convincingly demonstrated the existence of stem-cell niches and led to experiments to identify the niche-made signals that cause cells to become and remain self-renewing stem cells. Thus a stem-cell niche is a set of cells and the signals they produce, not just a location.

Intestinal Stem Cells Continuously Generate All the Cells of the Intestinal Epithelium

In humans, the epithelium lining the small intestine has a surface area of over 30 square meters and has two main functions: uptake of metabolites from digested food, and acting as a protective barrier

against toxins, bacteria, and other environmental stressors. It is a single cell thick (see Figure 20-11) and is composed of six types of differentiated cells: absorptive enterocytes, M cells, Tuft cells, Goblet cells, Paneth cells, and Enteroendocrine cells.

The most abundant epithelial cells, the absorptive enterocytes, transport nutrients essential for survival, such as glucose and amino acids, from the intestinal lumen into the body (see Figure 11-30). A network of capillaries underneath the epithelium transports these nutrients initially to the liver and ultimately to the rest of the body. The intestinal epithelium is the most rapidly self-renewing tissue in adult mammals, turning over every 5 days; in humans, up to 300 million intestinal epithelial cells, weighing a total of about 1 gram, are lost every day and need to be replenished.

The cells of the intestinal epithelium are continuously regenerated from a stem-cell population located deep in the intestinal wall in pits called *crypts* (Figure 22-14). Pulse-chase experiments using radiolabeled thymidine have shown that intestinal stem cells produce transit amplifying precursor cells that divide rapidly and then differentiate as they ascend the sides of crypts to form the surface layer of the fingerlike gut projections called *villi,* across which intestinal absorption occurs. The time from cell birth in the crypts to the loss of dead cells at the tips of the villi is only about 3 to 5 days (Figure 22-15). The production of new cells is precisely controlled: too little division would eliminate villi and lead to

breakdown of the intestinal surface; too much division would create an excessively large epithelium and might also be a step toward cancer. Paneth cells — a type of differentiated intestinal epithelial cells — are longer lived than the cells of the villi; they produce several antibacterial proteins, including the enzyme lysozyme, which degrades bacterial cell walls and thus protects the intestine from infections.

FIGURE 22-14 Intestinal stem cells and their niche. (a) Schematic drawing of an intestinal crypt and villus, showing the Lgr5-expressing ($\mathrm{Lgr5}^+$) intestinal stem cells (dark green), their mitotic progeny, the transit amplifying cells (intermediate blue), the terminal differentiating cells (light blue), and the several types of differentiated epithelial cells in the villus. The base of the crypt is the location of Paneth cells (yellow), which secrete antimicrobial defense proteins. The $+4$ cells (which occupy the fourth position from the crypt base, dark blue) can restore the $\mathrm{Lgr5}^+$ stem-cell compartment following injury. Telocytes are thin cells with long protrusions that form a three-dimensional network underlying the epithelial cells throughout the intestine, and are the major source of the Wnt and R-spondin hormones necessary for stem-cell self-renewal. (b) Lineages of cells in the small intestine and the extracellular signals that support specification of individual lineages. Epithelial turnover occurs every 3–5 days; new Paneth cells are produced from the transit amplifying cells every 3–6 weeks. $\mathrm{Lgr5}^+$ stem cells begin to differentiate as they are pushed out of the niche at the bottom of the crypt and the Wnt signal from telocytes is reduced. Depending on the extent of Notch signaling (Chapter 16) by adjacent cells they differentiate toward the absorptive (Notch on) or secretory fate (Notch off). Other hormones determine the subsequent specific fates of the absorptive or secretory transit amplifying progenitor cells into specific types of differentiated cells. The exact differentiation signals for Tuft cells are still not entirely understood; how different enteroendocrine subtypes are specified also is not yet well understood. See M. Shoshkes-Carmel et al., 2018, *Nature* **557**:242–246; and B. Degirmenci et al., 2018, *Nature* **558**:449–453.

EXPERIMENTAL FIGURE 22-15 Regeneration of the intestinal epithelium from stem cells can be demonstrated in pulse-chase experiments. Results from a pulse-chase experiment in which radioactively labeled thymidine (the pulse) was added to a culture of intestinal epithelial tissue. Proliferating cells incorporated the labeled thymidine into their newly synthesized DNA. After a brief period, the labeled thymidine was washed away and replaced with unlabeled thymidine (the chase); cells that underwent DNA replication after the chase did not become labeled. These micrographs show that 40 minutes after labeling, all of the label is in cells near the base of the crypt. At later times, the labeled cells are seen progressively farther away from their point of birth in the crypt. Cells at the top are shed. This process ensures constant replenishment of the gut epithelium with new cells.

After Cytotoxic Insult Are Not Dependent on Mitotic Activity," *Cell Tissue Kinet.* **6**:601–610; permission conveyed through Copyright Clearance Center, Inc.]

Experiments such as the one depicted in Figure 22-15 suggested that the intestinal stem cells were located somewhere near the bottom of the crypts, near Paneth cells, but these putative stem cells had no particular morphological characteristics that revealed their remarkable abilities. Which cells were the actual intestinal stem cells and which were the supportive cells that form the niche?

Wnt and R-Spondins Are Essential for Function of the $\mathbf{Lgr5^+}$ Intestinal Stem Cells

Prior genetic experiments had shown that Wnt signals are essential for intestinal stem cell maintenance. As evidence for the importance of these signals, overproduction of active β-catenin (normally activated by the Wnt signaling pathway; see Figure 16-26) in intestinal cells leads to excess proliferation of the intestinal epithelium. Conversely, blocking the function of β-catenin by mutating or inhibiting the Wnt-activated TCF transcription factor abolishes the stem cells in the intestine, leading to intestinal degeneration and eventual death. Thus Wnt signaling plays a critical role in the intestinal stem-cell niche, as it does in the skin, blood, and other organs. Indeed, mutations that inappropriately activate

the Wnt signaling pathway are a major contributor to the progression of colon cancer, as we will see in Chapter 25.

By analyzing a panel of genes whose expression in the intestine was induced by Wnt signaling, investigators zeroed in on *Lgr5*, a gene encoding a G protein–coupled receptor, because it was expressed only in a small set of cells at the very base of the crypts. Lgr5 binds a class of secreted hormones termed *R-spondins* and activates intracellular signaling pathways that potentiate Wnt signaling. Lineage-tracing studies showed that the descendants of these Lgr5-expressing cells indeed gave rise to all of the differentiated intestinal epithelial cells (Figure 22-16). These studies made use of genetically altered mice in which a version of the Cre recombination protein (see Figure 6-40), an estrogen receptor (ER)–Cre recombinase chimera, was placed under the control of the *Lgr5* promoter; the ER-Cre recombinase chimera was produced only in the few putative Lgr5-expressing stem cells at the bottom of the crypts. The version of Cre recombinase used in the study had been altered so that it resides inactive in the cytosol and is transferred into the nucleus only after addition of an estrogen analog (Figure 22-16a). There the Cre excises a blocking segment of DNA, activating expression of a β-galactosidase reporter gene. Importantly, all of the descendants of these cells will also express β-galactosidase. Immediately after addition of the estrogen analog, the only cells expressing β-galactosidase are the stem cells in the crypts. After a few days, all of the descendant epithelial cells also expressed β-galactosidase

(Figure 22-16b), showing that Lgr5 expression is indeed a marker of the intestinal stem cells.

EXPERIMENTAL FIGURE 22-16 Lineage-tracing studies show that the Lgr5-expressing cells at the bases of crypts are the intestinal stem cells. (a) Using genetically altered ES cells, investigators generated one strain of mice in which a version of the gene encoding Cre recombinase (see Figure 6-40) was placed under the control of the *Lgr5* promoter, and thus Cre recombinase was produced only in cells, such as intestinal stem cells, that express the *Lgr5* gene. This version of Cre recombinase contained an additional domain from the estrogen receptor (ER) that binds the estrogen analog tamoxifen; like the ER and other

nuclear receptors (see Figure 8-44), the ER-Cre chimera is retained in the cytosol unless the estrogen analog tamoxifen is added. In the presence of tamoxifen, ER-Cre moves into the nucleus, where it can interact with *loxP* sites in the chromosomal DNA. A second reporter strain of mice contained a bacterial β-galactosidase reporter gene that was preceded by two *loxP* sites. The blocking segment of DNA in between these *loxP* sites prevented expression of the β-galactosidase gene, and the β-galactosidase gene could be expressed only in cells where an active Cre recombinase had removed the sequence in between the two *loxP* sites. The two strains of mice were mated, and offspring containing both marker transgenes were identified. In these mice, β-galactosidase was expressed only in cells in which the Lgr5-controlled ER-Cre gene was expressed and only after tamoxifen was given to the mice. Thus only Lgr5-expressing cells — and all of their descendants — would express the β-galactosidase gene. (b) One day after tamoxifen was given to these mice, the only cells expressing β-galactosidase (indicated by the blue histochemical stain) were the few Lgr5-expressing intestinal stem cells at the bases of the crypts (*left*). Five days after tamoxifen administration, additional blue cells — the epithelial descendants of the intestinal stem cells — were seen migrating up the sides of the villi. Some blue stem cells remained at the bottom of the crypt.

In subsequent studies, single Lgr5-expressing stem cells were isolated from intestinal crypts and cultured on an extracellular matrix (see Figure 20-24) containing type IV collagen and laminin, similar to the matrix that normally underlies and supports the intestinal epithelia. These cells generated small villus-like structures that contained the four principal differentiated cell types found in the mature intestinal epithelium (Figure 22-17). Such miniature three-dimensional versions of an organ, produced in culture from some type of stem cell, are termed *organoids.* Organoids are used by

researchers to study the formation of many organs, including the human brain, and to develop treatments for many diseases.

EXPERIMENTAL FIGURE 22-17 Single Lgr5-expressing intestinal stem cells build crypt-villus organoid structures in culture without niche cells. Single Lgr5-expressing cells isolated from intestinal crypts were placed in culture on a type IV extracellular matrix (see Figure 20-24). After 2 weeks, these cultures had formed epithelial sheets that resembled villi in structure. Staining of these organoids for specific marker proteins showed that they contained all four differentiated epithelial cell types: (a) villin (green) is a marker protein for the absorptive enterocytes that are localized near the apical (luminal, Lu) surface of these organoids; (b) Muc2 (red) for goblet cells; (c) lysozyme (green) for Paneth cells; and (d) chromogranin A (green) for enteroendocrine cells. The organoids were also stained with DAPI (blue) to reveal nuclei.

[Reprinted with permission from Nature Publishing Group, from T. Sato et al., 2009, "Single Lgr5 Stem Cells Build Crypt-Villus Structures In Vitro Without a Mesenchymal Niche," *Nature* **459**(7244):262–265; permission conveyed through Copyright Clearance Center, Inc.]

Taken together, these experiments established that expression of the *Lgr5* gene defines the intestinal stem cells and showed that these cells are localized at the bases of the intestinal crypts interspersed between the terminally differentiated Paneth cells (see Figure 22-

14a). Lgr5-expressing cells are also found in the stomach, colon, and pancreas — which, like the small intestine, are formed from the embryonic endoderm — and are thought to be the stem cells for these tissues. Indeed, culturing Lgr5-expressing cells from these tissues in the presence of Wnt, R-spondin, and other hormones generates organoids that contain differentiated cells characteristic of these tissues.

Telocytes — thin fibroblast-like cells with long protrusions that surround the sheet of epithelial cells throughout the intestine (see Figure 22-14a) — are the major source of both Wnt and R-spondins, hormones essential for normal function of the Lgr5-expressing stem cells. Paneth cells also secrete Wnt and were once thought to be the major Wnt-producing intestinal cells, but knocking out Wnt expression in all intestinal epithelial cells, including Paneth cells, had no effect on intestinal stem cells or renewal of intestinal epithelial cells. In contrast, conditional ablation in mouse telocytes of the porcupine gene, which is required for functional maturation of all Wnt proteins, caused a rapid cessation of Wnt signaling to intestinal crypts, followed by loss of proliferation of stem and transit amplifying cells and impaired epithelial renewal. Thus telocytes surrounding the base of the crypts are the principal source of the Wnt and R-spondin self-renewal signals to intestinal stem cells. These cells also produce EGF and TGFα, two hormones in the epidermal growth factor family that are also required for $Lgr5^{+}$ stem cell function.

Lgr5-expressing cells are not the only type of intestinal stem cells. Evidence indicates that so-called +4 cells located in the crypts (see Figure 22-14a) are reserve stem cells that can generate Lgr5-expressing stem cells following intestinal injury, such as by irradiation. Recall that transit amplifying cells have limited self-renewal potential (see Figure 22-11). During periods of intestinal injury, when many Lgr5-expressing stem cells are lost, some of the transit amplifying cells, under the influence of Wnt signals, can *dedifferentiate* — reverting to Lgr5-expressing stem cells and relocalizing to the stem cell niche at the base of the crypts! Thus the conversion of differentiated cells into stem cells, as seen experimentally during formation of iPS cells, may occur normally in the body during periods of stress or injury. As such, rather than relying on a single stem cell-to-differentiated cell lineage (see Figure 22-14b), the intestine seems capable of drawing on a pool of reserve stem-cell populations. Future work will undoubtedly clarify the role of these cells in generating intestinal epithelial cells.

Hematopoietic Stem Cells Form All Blood Cells and All Cells of the Immune System

All red and white blood cells and virtually all cells that form the immune system need to be continuously replenished. Human red blood cells survive 90–120 days before they are degraded by

macrophages, mainly in the spleen. Macrophages can survive for several months while neutrophils survive only a few days. All of these cells derive from a single type of multipotent, self-renewing *hematopoietic stem cell (HSC)* through multiple transit amplifying cell divisions leading to multipotent and then unipotent progenitors (Figure 22-18).

FIGURE 22-18 Formation of blood cells from hematopoietic stem cells in the bone marrow. Early in mammalian development, multipotent hematopoietic stem cells often divide symmetrically to increase the numbers of stem cells. In adults, they generally divide

asymmetrically to form one daughter cell that is multipotent, like the parent stem cell, and another daughter cell with a more restricted fate. Recent single-cell sequencing of purified progenitor populations revealed an unanticipated heterogeneity; there are at least 18 distinct subtypes of transit-amplifying hematopoietic progenitors. These multipotent transit amplifying cells are likely capable of limited numbers of self-renewal divisions but, depending on the types and amounts of cytokines present, they undergo rapid rounds of cell division and generate different types of progenitor cells (light green). These progenitors are either multipotent (e.g., bipotential granulocyte — monocyte and erythroid — megakaryocyte progenitors) or unipotent in that they can give rise to more than one type or only a single type of differentiated blood cells, respectively; they respond to one or a few specific cytokines. The lymphoid branch has not yet been studied in such great detail with single cell transcriptomics; future work should reveal more about how the B, NK, and T cells of the immune system (Chapter 24) are specified. Some of the cytokines that support this process are indicated (pink labels). CSF = colony-stimulating factor; IL = interleukin; SCF = stem-cell factor; Epo = erythropoietin; Tpo = thrombopoietin. See S. Watcham, I. Kucinski, and B. Gottgens, 2019, *Blood* **133**:1415.

Characterizing Hematopoietic Stem Cells by Transplantation

Characterization of HSCs and the more restricted progenitors they generate was much more difficult than defining the germ or intestinal stem cells discussed earlier, as these stem cells are localized to niches that have a specific location in tissues (see Figures 22-13 and 22-14). Like all stem cells, hematopoietic stem cells are found in niches, but in embryos HSCs are dispersed among fetal liver cells and in adults HSCs and their niche cells are scattered among many other types of cells within the bone marrow. Identifying HSCs and the cells that make up the HSC niche was also

difficult because HSCs comprise only about 0.01 percent of bone marrow or fetal liver cells.

Hematopoietic stem cells and the progenitors they generate were originally detected and quantified by bone marrow transplantation experiments in mice whose hematopoietic stem and progenitor cells had been eradicated by irradiation (Figure 22-19). Purification of HSCs was difficult since no cell-surface protein is expressed only by HSCs, and thus no exclusive surface marker was available for these cells. However, much work showed that HSCs could be prospectively identified and partially purified because they do express cell-surface proteins called *CD150* and *Sca-1* (of unknown functions) and do not express any of the dozen or so *Lin (Lineage-restricted)* marker proteins found on the surface of specific types of differentiated hematopoietic cells. Further efforts took advantage of the fact that HSCs require a growth factor termed *stem-cell factor (SCF)* for their survival; this protein, which is produced as the extracellular domain of a membrane-spanning protein and is localized to the surface of an adjacent signaling cell, activates the c-Kit protein tyrosine kinase receptor on HSCs. HSCs also require CXCL12, a chemoattractant for HSCs that binds to a G protein–coupled receptor on HSCs and is required to keep HSCs in the niche. CXCR4, the receptor for CXCL12, is also found on HSCs.

EXPERIMENTAL FIGURE 22-19 Functional analysis of mouse hematopoietic stem cells by bone marrow transplantation. The two strains of mice used in this analysis are genetically identical except for the gene encoding a protein, termed *Ly5*, found on the surfaces of all nucleated blood cells, including all T and B lymphocytes, granulocytes, and monocytes. The proteins encoded by the two alleles of the gene, Ly5.1 and Ly5.2, can be detected by specific monoclonal antibodies. A recipient Ly5.2 mouse is lethally irradiated to kill all HSCs, clearing out the stem-cell niches in the bone marrow so they can receive stem cells from a donor mouse; the mice are then injected with stem cells purified from a Ly5.1 strain. Because the stem cells take weeks or months to produce differentiated blood cells, the recipient mouse will die unless it receives bone marrow progenitor cells from a genetically identical Ly5.2 mouse (termed "supportive" cells) that will produce mature blood and immune system cells for the first few weeks after the transplant. At intervals after the transplant, blood or bone marrow is recovered and reacted with a blue-fluorescing monoclonal antibody to Ly5.1 and a red-fluorescing monoclonal antibody to Ly5.2. Mature blood cells that are descended from the donor stem cell are detected by FACS analysis, seen here as cells that fluoresce blue and not red. These cells can be sorted and stained with fluorescent antibodies specific for marker proteins found on different types of mature blood cells to show that a stem cell is indeed pluripotent, in that it can generate all types of lymphoid and myeloid cells.

Thus HSCs could be purified first by treating bone marrow cells with magnetic beads coated with a series of monoclonal antibodies each specific for a Lin protein on the surface of differentiated hematopoietic cells, and then removing all of the lineage-positive differentiated cells attached to the beads with a magnet. Next the remaining lineage-negative cells were treated with fluorescent antibodies for c-Kit, CD150, and Sca-1, and the few cells that expressed all of these marker proteins were separated in a fluorescence-activated cell sorter (FACS; see Figures 4-1 and 4-2) and used in transplantation experiments.

Remarkably, such transplantation studies revealed that a single HSC is sufficient to restore the entire blood system when transferred into a lethally irradiated mouse in which all of its HSCs had been killed. After transplantation, the HSC takes up residence in a niche in the bone marrow and divides to make more HSCs as well as progenitors of the different blood-cell lineages.

The first successful human bone marrow transplant was done in 1959, when a patient with end-stage (fatal) leukemia was irradiated to destroy her cancer cells as well as her own normal HSCs. She was transfused with bone marrow cells from her identical twin sister, thus avoiding an immune response, and was in remission for 3 months. This pioneering effort, which was awarded a Nobel Prize in Medicine in 1990, led to the present-day treatments that can often lead to a complete cure of many diseases. Because stem cells in the transplanted marrow can generate all types of functional blood cells as well as all cells of the immune system, transplants using bone marrow HSCs from normal donors are useful in patients with several hereditary anemias, including β-thalassemia (caused by mutations that lead to production of reduced amounts of the hemoglobin β chain) and sickle-cell disease (caused by a point mutation in the β chain of hemoglobin), as well as patients with diseases such as X-linked Severe Combined Immune Deficiency (SCID), in which the gene for the IL-2 receptor common gamma chain (see Figure 16-19b) is inactivated and no immune cells are produced. Transplants are also used to treat many cancer patients

who have received irradiation or chemotherapy, both of which destroy bone marrow cells as well as cancer cells.

Patients with β-thalassemia, SCID, and sickle-cell disease can now be treated by a combination of gene therapy and an autologous bone marrow transplant. Cell populations containing HSCs are removed from the patient, treated in culture with a lentiviral vector (a type of retrovirus derived from HIV; see Figure 6-35) into which a normal copy of the mutant gene had been inserted, and the corrected HSCs transfused back into the patient. ■

Niches for Hematopoietic Stem Cells and Many Hematopoietic Progenitor Cells

During embryonic life, mammalian HSCs reside in the liver and often divide symmetrically, producing two daughter stem cells (see Figure 22-12b); this process allows the number of stem cells to increase over time and produce the large number of progenitor cells required to make all of the necessary blood cells before birth. Hepatocyte progenitors are the major cell that forms the HSC niche in the fetal liver. These cells express SCF and other proteins required for HSC survival. Co-culture of these hepatic progenitor cells with HSCs led to expansion of HSC numbers as well as formation of their differentiated progeny, solidifying their role as HSC niche cells.

In adult mammals, HSCs reside in the bone marrow and are largely quiescent, resting in the G_0 state in the bone marrow stem-cell niche. When more blood cells are needed, cytokines are generated locally, which signals some HSCs to divide, producing stem cells like the parent cells and rapidly proliferating transit amplifying cells that generate the progenitors depicted in Figure 22-18. Whether individual HSCs undergo symmetric or asymmetric divisions is not known.

A small number of mesenchymal cells surround the small blood vessels, termed *sinusoids*, that permeate the bone marrow. Some of these cells are termed *leptin receptor positive* as they express the receptor for the cytokine leptin on their surface. They also express large amounts of SCF, synthesize abundant CXCL12, and are thought to be the major HSC niche cells in the bone marrow (Figure 22-20a). Immunofluorescence analysis showed that about 85 percent of HSCs physically contact these cells (Figure 22-20b). Other cells in the bone marrow probably influence stem-cell maintenance or niche function by releasing other types of hormones.

EXPERIMENTAL FIGURE 22-20 The hematopoietic stem-cell niche in the bone marrow. (a) The bone marrow contains dozens of different types of cells, including osteoblasts and osteoclasts that build and degrade bone, respectively, as well as multiple types of hematopoietic stem and progenitor cells, and other cell types. The bone marrow is permeated by small blood vessels termed *sinusoids*. The predominant cells that form the HSC niche are the very rare mesenchymal stromal cells that adhere to these vessels and that express a combination of cell-surface proteins including the leptin receptor $(\mathrm{LepR} + \mathrm{cells})$ and SCF, the hormone that binds to and activates the c-Kit protein tyrosine kinase receptor on HSCs and many types of hematopoietic progenitor cells. The stromal cells also secrete CXCL12, a chemoattractant for HSCs, and the $\mathrm{LepR} + \mathrm{cells}$ also act as supportive niche cells for a number of hematopoietic progenitor cells depicted in Figure 22-18. MEP = megakaryocyte erythroid progenitor; GMP = granulocyte macrophage progenitor; CFU-E = colony forming unit erythroid–erythrocyte progenitor. See S. J. Morrison and D. T. Scadden, 2014, *Nature* **505**:327; and S. Comazzetto et al., 2019, *Cell Stem Cell* **24**:477. (b–d) Immunofluorescence detection of HSCs and niche cells in bone marrow, showing that HSCs are localized next to SCF-expressing cells. Antibodies to SCF were not available, so in order to detect SCF expression, a mouse was generated in which GFP cDNA was placed in the SCF gene locus and expressed only in cells that normally produce SCF. (b) Bone marrow sections were then examined in a fluorescence microscope to detect the SCF-expressing cells. (c) To

detect HSCs, the sections were stained with an antibody to the CD150 protein, expressed on the surface of HSCs. (d) The sections were also stained with a collection of antibodies specific for proteins expressed on the surface of specific types of differentiated blood cells, but not by HSCs. (e) When the three images are merged, an HSC (white arrows) can be seen adjacent to the SCF-expressing stromal cell.

[Parts (b–e) reprinted with permission from Nature Publishing Group, from L. Ding et al., 2012, "Endothelial and Perivascular Cells Maintain Haematopoietic Stem Cells," *Nature* **481**(7382):457–462; permission conveyed through Copyright Clearance Center, Inc.]

Like HSCs, a number of hematopoietic precursors also require SCF for their proliferation and differentiation and express c-Kit, the SCF receptor, on their surface. These cells — including many of the multipotent progenitors formed from HSCs, as well as megakaryocyte-erythrocyte progenitors, and granulocyte-macrophage progenitors — are also found in the bone marrow adjacent to the leptin receptor positive cells that express SCF. Indeed, conditional deletion of SCF from these leptin receptor positive cells depleted all of these progenitors and their descendants from the bone marrow. Thus many hematopoietic progenitors as well as HSCs require specific types of bone marrow niche cells for their survival and function.

Regulating the Production of Differentiated Hematopoietic Cells

In adults, HSCs rarely divide, but when they do, on average one of the daughters remains a stem cell like the parent (self-renewal)

while the other divides rapidly and eventually gives rise to one of several multipotent progenitors. These are more restricted in their fates and like transit amplifying cells in other lineages (see Figure 22-11) are capable of a limited number of self-renewal divisions before giving rise to lineage-specific progenitor cells, each of which in turn can divide and generate multiple numbers of a specific type of differentiated cell (see Figure 22-18).

Numerous extracellular growth factors termed **cytokines** regulate HSC self-renewal divisions as well as proliferation and differentiation of the precursor cells for various blood-cell lineages (see Chapter 16). Each branch of the blood-cell lineage tree is affected by different cytokines, allowing exquisite control of the production of specific cell types. If all blood-cell types are needed — for example, after a bleeding injury — multiple cytokines can be produced. If only one cell type is needed, specific signals control its production. For example, when a person is traveling at high altitude, *erythropoietin* is made by the kidneys and stimulates the proliferation and differentiation of CFU-E (erythroid progenitor) cells, but not other types of blood-cell precursors. The erythropoietin receptor is expressed only in erythroid precursors and activates intracellular signal transduction pathways that lead to induction of ~400 genes essential for formation of a mature red blood cell (see Figure 16-18). Similarly, G-CSF, a different cytokine, stimulates proliferation of bipotential granulocyte-macrophage progenitors and their differentiation into granulocytes, while M-CSF

stimulates production of macrophages from the same progenitor cell type (see Figure 22-18).

By transplanting specific types of hematopoietic precursors into mice and observing which blood cells were produced, researchers could infer which precursors or terminally differentiated cells (e.g., erythrocytes, monocytes) arise from a particular type of precursor. Colony-forming assays can also determine the potential fates of progenitor cells; individual progenitor cells are cultured in a semisolid matrix such as methyl cellulose, together with a group of cytokines. All of the daughter cells produced remain localized together, forming a colony of cells. From the types of differentiated cells in the colony one can infer the identity of its progenitor.

These experiments gave rise to the notion that there are discrete states of hematopoietic stem and progenitor cells, and as these cells underwent differentiation their transcriptomes would change from one defined discrete state to another. Single-cell sequencing, with its ability to analyze the transcriptomes of multiple individual cells, has modified this understanding of hematopoiesis. Because some HSCs express transcription factors required for lymphoid (immune system) differentiation and others essential for myeloid (red and white blood cell) differentiation, some HSCs are thought to be programmed to differentiate toward the lymphoid or myeloid pathways. Rather than cellular transitions between discrete progenitor states, such as between a granulocyte/monocyte progenitor and differentiated granulocytes or monocytes, multiple

studies have supported the idea of continuous differentiation pathways, with gradual changes in the transcriptomes from one differentiating cell state to another (see Figure 22-18).

🌿 Meristems Are Niches for Stem Cells in Plants

In plants, as in their multicellular animal counterparts, the production of all tissues and organs relies on small populations of stem cells. Like animal stem cells, these stem cells are defined by their ability to undergo self-renewal and to generate daughter cells that produce differentiated tissues. Also like animal stem cells, plant stem cells reside in stem-cell niches — specialized microenvironments where extracellular signals are produced that maintain the stem cells in a multipotent state. Because the last common ancestor of plants and animals was a unicellular eukaryote, it would appear that, despite common organizing principles, stem cells and their niches evolved independently and by different pathways in plants and animals — an example of *convergent evolution*.

The niches in which plant stem cells are located, called **meristems**, can persist for thousands of years in long-lived species such as bristlecone pines. The body axis of the plant is defined by two primary meristems that are established during embryogenesis, the

shoot apical meristem and the *root apical meristem*. In contrast to animal development, very few tissues or organs are specified during plant embryogenesis. Instead, organs such as leaves, flowers, and even germ cells are continuously generated as the plant grows and develops. The aboveground part of the plant is derived from the shoot apical meristem and the belowground part from the root apical meristem. Classic clonal analysis experiments have demonstrated that plant-cell fate depends on the cell's position, not its lineage. A cell's identity is reinforced by intercellular signals such as hormones, mobile signaling peptides, and miRNAs. ■

Unlike somatic stem cells in metazoan animals, somatic plant stem cells give rise to entire organs, not just specific tissues or lineages. Slowly dividing pluripotent stem cells are located at the apex of the shoot apical meristem, with more rapidly dividing multipotent transit amplifying daughter cells on the periphery. Descendants of the shoot stem cells are displaced to the periphery of the meristem and are recruited to form primordia of new organs, including leaves and stems. Division ceases as these cells acquire the characteristics of specific cell types, and most organ growth occurs by cell expansion and elongation (Figure 22-21a). New shoot stem-cell niches can form in the axils of leaf primordia, which then grow to form lateral branches. Floral meristems give rise to the four floral organs — sepals, stamens, carpels, and petals — that form flowers. Unlike shoot apical meristems, floral meristems gradually become depleted as they give rise to the floral organs.

FIGURE 22-21 Structures of the *Arabidopsis thaliana* shoot and root meristems. (a) Transverse section through the apex of the shoot apical meristem. The organizing center cells signal to maintain the overlying stem cells. The stem cells produce daughters by division in the direction of the black arrows, generating rapidly dividing transit amplifying cells that will eventually differentiate and give rise to entire organs, such as a leaf. (b) Transverse section through the root meristem. Stem cells surround the mitotically less active quiescent center, four cells that send signals to prevent stem-cell differentiation. Each stem cell divides asymmetrically: one daughter remains adjacent to the quiescent center and becomes a stem cell (self-renewal); the other daughter becomes a transit amplifying cell that divides a number of times before exiting the cell cycle, elongating, and assuming a specific differentiated state.

A Negative Feedback Loop Maintains the Size of the Shoot Apical Stem-Cell Population

Genes required for stem-cell identity, maintenance, and cell differentiation have been defined by genetic screens in the mustard-family weed *Arabidopsis thaliana* (see Figure 1-23h) for mutants exhibiting larger, smaller, or non-replenishing meristems, as well as by more recent gene-expression profiling studies of isolated meristem-cell populations. One shoot apical meristem determinant is the gene called *WUSCHEL (WUS)*, which encodes a homeodomain transcription factor (see Chapter 8). *WUS* is required for maintenance of the stem-cell population but is expressed in the supportive cells underlying the stem cells. These cells, collectively termed the *organizing center*, are analogous to the niche cells in metazoans (see Figure 22-21a). While *WUS* mRNA and protein are synthesized in the cells of the organizing center, WUS moves from the organizing-center cells into the stem cells, presumably through the interconnecting plasmodesmata (see Figure 20-43). In one study, a WUS-GFP fusion protein, when expressed in *WUS*-negative *Arabidopsis* plants, was able to rescue the mutant phenotype. Subsequent microscopic analysis showed that this WUS-GFP chimera accumulated in the stem cells, indicating it had moved there from the organizing-center cells.

Once in the stem cells, WUS binds to many sites in the genome; it represses a large number of genes that are expressed in differentiating cells, including a group of differentiation-promoting transcription factors required for leaf development. WUS also directly activates the expression of *CLAVATA3 (CLV3)* in stem cells. *CLV3* encodes a small, secreted peptide that binds to the CLV1 receptor on the surface of organizing-center cells and generates an intracellular signal that negatively regulates WUS expression. Overexpression of WUS causes a large expansion of the meristem stem-cell population at the expense of production of differentiated cells. Thus the negative feedback loop between a transcription factor, WUS, and a signaling peptide, CLV3, maintains the size of the stem-cell population and the number of their dividing daughter cells over the lifetime of the plant (Figure 22-22). ■

FIGURE 22-22 Regulatory network in the *Arabidopsis* shoot meristem stem-cell niche. The transcription factor WUS (orange circles) is synthesized in the organizing-center cells and moves via plasmodesmata into stem cells, where one of its functions is to induce expression of the CLV3 hormone (green circles). Secreted CLV3 protein binds to CLV1, the CLV3 receptor protein kinase on the surface of organizing-center cells; there it activates a signal that represses *WUS* transcription. See E. Aichinger et al., 2012, *Annu. Rev. Plant Biol*; **63**:615.

[Data from R. Heidstra and S. Sabatini, 2014, *Nat. Rev. Mol. Cell Biol.* **15**:301.]

Several other transcriptional regulatory proteins are essential for the normal function of both shoot and root meristem cells, including the plant homolog of the human retinoblastoma (Rb) tumor suppressor protein (see Chapter 25), called *RBR*. As in animal cells, RBR binds to and inhibits the function of an E2F transcription factor; release of RBR from E2F or genetic loss of RBR allows the E2F factor to promote transcription of multiple genes that promote entry into the cell cycle and cell division (see Figure 19-16). Reduced levels of RBR result in an increase in stem-cell numbers, and increased RBR levels lead to stem-cell differentiation; both of these observations indicate a prominent role for RBR in stem-cell maintenance.

The Root Meristem Resembles the Shoot Meristem in Structure and Function

Unlike the shoot meristem, the root meristem consists of lineage-restricted stem cells. These cells are organized around the *quiescent center*, four very slowly dividing cells that serve as the stem-cell niche (Figure 22-21b). Stem-cell division is asymmetric (also unlike that in the shoot), and the daughter cell that loses contact with the quiescent center divides several more times and then differentiates. A WUS homolog, WOX5, is expressed in the quiescent center and is required for stem-cell maintenance, although other

transcription factors are also important. The plant hormone auxin (indole-3-acetic acid) coordinates many processes involved in plant growth and differentiation; in particular, it is essential for formation of the root meristem niche. If the quiescent center is ablated, a new niche is formed in an area of high auxin concentration. However, the effect of auxin on stem cells depends on the specific cell type. For example, in the stem cells that give rise to the root cap, auxin promotes cell differentiation by repressing *WOX5* via auxin-responsive transcription factors.

Plants have an amazing capacity for regeneration. The home gardener will be familiar with the ability of some leaf or stem cuttings to form roots with little inducement beyond a glass of water and a sunny windowsill. Experiments performed in the mid-twentieth century demonstrated that single cells isolated from carrot roots could regenerate entire plants when placed on media containing the appropriate mix of nutrients and hormones. Recent studies have utilized detailed molecular analyses, including sequencing the transcriptomes of single cells and lineage tracing, to the process of regeneration. In some instances, regeneration appears to follow a program similar to the embryonic processes that initially establish meristems. For example, excision of the root tip removes the quiescent center and disrupts the auxin gradient. An auxin maximum is then established at the new distal tip via polar auxin transport. *WOX5* initially exhibits a broad expression domain but gradually becomes restricted to a newly formed quiescent center

as hormone gradients are reestablished and the meristem is reconstructed. ■

KEY CONCEPTS OF SECTION 22.2

Stem Cells and Niches in Multicellular Organisms

- Planaria contain pluripotent stem cells termed *cNeoblasts* that are important for regeneration of body parts removed by amputation.
- Most stem cells in animals are multipotent, except for germ-line stem cells that are unipotent.
- Stem cells are undifferentiated; they can undergo symmetric or asymmetric self-renewal divisions such that their number remains constant or increases over the organism's lifetime (see Figure 22-12).
- Stem cells are formed in niches that provide signals to maintain a population of undifferentiated stem cells. The niche must maintain stem cells without allowing their excess proliferation and must block differentiation.
- Stem cells are prevented from differentiating by specific controls that operate in the niche. A high level of β-catenin, a component of the Wnt signaling pathway, has been implicated in preserving stem cells in the germ line and intestine by directing cells toward self-renewal division rather than differentiation states.
- In the *Drosophila* germarium, a few cells form the germ stem-cell niche, sending signals directly to the adjacent stem cells. Daughter cells that are displaced from the niche cells undergo proliferation and differentiation into germ cells (see Figure 22-13).
- Populations of stem cells associated with the intestinal epithelium and many other tissues regenerate differentiated tissue cells that are damaged, sloughed, or aged (see Figure 22-14).
- Intestinal stem cells reside in the bases of intestinal crypts, adjacent to Paneth cells, and are marked by expression of the Lgr5 receptor (see Figure 22-14).
- In the blood-cell lineage, different precursor types form and proliferate under the control of distinct cytokines (see Figure 22-18). This system allows the body to specifically induce the replenishment of some or all of the necessary blood-cell types.
- Hematopoietic stem cells can be detected and quantified by bone marrow transplant experiments (see Figure 22-19) and their niche cells detected using a combination of marker surface proteins (see Figure 22-20).
- Plant stem cells persist for the life of the plant in the meristem. Meristem cells can give rise to a broad spectrum of cell types and structures (see Figure 22-21).

- A negative feedback loop involving the WUS transcription factor maintains the size of the shoot apical stem-cell population.

22.3 Mechanisms of Cell Polarity and Asymmetric Cell Division

We have discussed the importance of asymmetric division in generating cell diversity during development and in maintaining the number of stem cells in a population. What mechanisms underlie the ability of cells to become asymmetric before cell division to give rise to cells with different fates? Cell asymmetry is a concept we have encountered before, under the name of *cell polarity*, so let us first review what it means for a cell to be polarized.

Cell polarity — the ability of cells to organize their internal structure, resulting in changes in cell shape and the generation of regions of the plasma membrane with different morphologies and protein and lipid compositions — has been introduced in several chapters. For example, we have seen that polarized intestinal epithelial cells have an apical domain with abundant microvilli separated from the basolateral domain by tight junctions (see Figures 17-1 and 20-11). Epithelial transport requires these cells to have different transport proteins in the apical and basolateral membranes (see Figure 11-30). As we discuss later in this section, these epithelial cells are responding to extracellular signals that instruct them how to polarize. These cells represent just one example of cell polarity — essentially all cells in animals are polarized, and we discuss several examples in which the underlying mechanisms have been defined. What emerges are three core principles of cell polarity. First, cells

have an *intrinsic polarity program*, as revealed by their remarkable ability to polarize in the absence of external cues. As we will see in our examples, a master and common regulator of this program is the small GTPase Cdc42. Second, this intrinsic polarity program can be directed by external or internal *cues*. Third, the polarity of individual cells is often maintained by intracellular *mutually antagonistic complexes*.

We first discuss the intrinsic polarity program in budding yeast because, given that all the components of the mechanism are shared with animals, the principles uncovered in yeast are likely to be conserved. We then turn our discussion to examples in which cells respond to external cues to establish cell polarity depending on antagonistic interactions. Finally, we discuss an example of asymmetric cell division that gives rise to a daughter stem cell and a differentiated cell.

The Intrinsic Polarity Program Depends on a Positive Feedback Loop Involving Cdc42

Budding yeast grows by selecting a single site on its surface at which to assemble a new bud (see Figure 19-4). Importantly, it must reliably select just one site. If a cell grew two buds simultaneously, during mitosis the duplicated chromosomes might be segregated

between the parent cell and one bud, leaving the other bud without chromosomes and therefore inviable. In haploid yeast, this so-called singularity of budding is guided by a signal, or cue, left at the cell surface, which directs the next budding event to a site adjacent to the former budding site. Remarkably, if the genes that specify the nonessential components of this cue are deleted, yeast cells grow just as well, but each assembles a single bud at a random site. Thus yeast has an intrinsic polarity program that, even in the absence of cues from the previous budding cycle, can guide selection of a single site for bud growth. This program requires the concentration of Cdc42 at the site from which a bud will emerge.

Surprisingly, Cdc42 concentration at the site for a new bud does not depend on either actin filaments or microtubules, as this small GTPase localizes to a single spot even when both filament systems are disrupted (Figure 22-23a). Long before biologists had thought about how this might occur, the brilliant mathematician and computer pioneer Alan Turing considered what mechanism might shift a uniform distribution of a factor to a concentration at a single site. In 1952, Turing suggested that such a shift could be achieved if a positive feedback reaction amplified a random increase in the concentration of the polarity factor — and he was right!

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

FIGURE 22-23 The intrinsic polarity program of budding yeast involves a positive feedback loop for activation of the GTPase Cdc42. (a) Diploid yeast lacking polarity cues show polarized Cdc42, visualized here by immunofluorescence microscopy, when they are about to assemble a bud. The cells were treated with drugs to disassemble both actin filaments and microtubules to show that polarization of Cdc42 is not dependent on these cytoskeletal filaments. (b) Positive feedback loop for activation of Cdc42. Inactive Cdc42·GDP is in equilibrium between a cytosolic pool of complexes with the guanine nucleotide dissociation inhibitor (GDI) and a membrane-bound pool. Step 1: One of the membrane-associated Cdc42·GDP proteins may spontaneously become an activated Cdc42·GTP. Step 2: Active Cdc42·GTP recruits a complex containing the guanine nucleotide exchange factor (GEF). Step 3: The recruited GEF now locally converts more Cdc42·GDP to Cdc42·GTP. Step 4: This active Cdc42·GTP recruits more GEF, driving a

positive feedback loop that results in the local accumulation of Cdc42·GTP (visualized as bright red puncta). See J. G. Chiou, M. K. Balasubramanian, and D. J. Lew, 2017, *Annu. Rev. Cell Dev. Bi.* **33**:77.

[Part (a) reprinted with permission from Nature Publishing Group, from J. E. Irazoqui, A. S. Gladfelter, and D. J. Lew, 2003, "Scaffold-Mediated Symmetry Breaking by Cdc42p," *Nat. Cell Biol.* **5**(12):1062–1070; permission conveyed through Copyright Clearance Center, Inc.]

Recall that Cdc42 is a member of the Rho family of small GTP-binding proteins (see Figure 17-40). It acts as a molecular switch, existing in an inactive (Cdc42·GDP) and an active membrane-bound (Cdc42·GTP) state. Binding to its specific guanine nucleotide exchange factor (Cdc42-GEF) causes Cdc42 to release GDP and bind GTP. The active Cdc42·GTP binds many effectors and thereby activates downstream signaling events. In its inactive state, Cdc42·GDP exists in equilibrium between a cytosolic pool, which is bound to a guanine nucleotide dissociation inhibitor (GDI), and a membrane-bound Cdc42·GDP pool (Figure 22-23b). Occasionally and randomly, the membrane-bound Cdc42·GDP will release its GDP and bind GTP, which converts it to the active Cdc42·GTP state (Figure 22-23b, step **1**). One of the effectors that is recruited to Cdc42·GTP is a protein complex that contains the Cdc42-GEF (Figure 22-23b, step **2**). Thus when an active Cdc42 arises in the plasma membrane, it recruits Cdc42-GEF, which locally activates more Cdc42, which recruits more Cdc42-GEF, and this simple positive feedback loop generates a site on the cell surface that is highly and locally enriched for Cdc42·GTP (steps **3** and **4**). Computational modeling — also pioneered by Turing — shows that this system can result in a

winner-takes-all scenario to yield just one site of polarization. This positive feedback loop is the core mechanism by which one budding site is generated in yeast.

As we discussed in Chapter 18, Cdc42 is the master regulator that guides the polarization of migrating cells (see Figure 18-54) and is also involved in regulating many additional examples of cell polarity. It is important to note that in cases in which polarization needs to be flexible, negative feedback loops ensure that the single site of polarization is not too strong, so that it can be redirected to another site on the cell surface upon receiving appropriate signals. For example, in addition to its fast-acting GEF, Cdc42·GTP might also recruit a slow-acting negative regulator that modulates the degree of positive feedback. In fact, yeast Cdc42 recruits a kinase that phosphorylates and inhibits the recruited Cdc42-GEF, thereby introducing a negative feedback loop. Thus the local concentration of Cdc42·GTP builds up fast, then levels off or disappears as the slower negative regulator comes into play. As we will see, specific cues normally guide these intrinsic polarity programs, which in turn lead to the physical polarization of the cell.

Cell Polarization Before Cell Division Follows a Common Hierarchy of Steps

The polarization of a cell, with or without cell division, follows the general pattern diagrammed in Figure 22-24a. In order to know in which direction to polarize, or become asymmetric, a cell generally senses specific cues that provide it with spatial information (step **1**). Such cues can be soluble signals from other cells or from the extracellular matrix. To be receptive to these cues, a cell must have appropriate receptors or other machinery on its surface (step **2**). Once the cues have been detected, the cell responds by feeding the incoming signal into its polarity program to define the orientation of polarity (step **3**). Generally the next step involves the local reorganization of cytoskeletal elements, notably microfilaments and microtubules (step **4**). Once the cell has structural asymmetry, molecular motors direct the trafficking of polarity factors — which, depending on the system, may be cytoplasmic proteins or membrane proteins synthesized by the secretory pathway, or both — to their appropriate locations (step **5**). The polarity can be reinforced or maintained by moving the polarity determinants from sites of lower concentration back to the polarization site to maintain the highest concentration there (step **6**).

FIGURE 22-24 General features of cell polarity and asymmetric cell division. (a) General hierarchy of the steps in generating a polarized cell. See text for details. (b) To generate cells with different fates, specific determinants, including mRNAs, proteins, and lipids, must be asymmetrically distributed in a cell. If the mitotic spindle is positioned so that these determinants are segregated during cell division, the two daughter cells will have different fates. However, if the mitotic spindle is not oriented appropriately, the determinants will not be segregated properly, and the daughter cells could have the same fate (not shown).

If a cell becomes polarized and cell division then occurs in a plane perpendicular to the direction of polarization, the cell has undergone asymmetric cell division. In this way, fate determinants,

such as specific proteins or mRNAs, can be differentially segregated between the cells (Figure 22-24b).

Cell polarization can be a very dynamic process. Consider a macrophage chasing a bacterium in order to catch and destroy it by phagocytosis: the macrophage must continually sense the bacterium, which it does by following a gradient of a peptide left by the bacterium (see Figure 17-45). This signal orients — or polarizes — the macrophage to move in the correct direction. This example highlights an important and common aspect of cell polarity: in many cases, it must be dynamic so that it can quickly change direction. Although we have illustrated the dynamics of cell polarity in terms of a macrophage, the polarity of epithelial and other cells that appear very static is probably quite dynamic when those cells are moved to different environments.

In the next section, we discuss a simple cell that shows asymmetry: a yeast cell responding to a soluble cue during mating. In later sections, we turn to animal cells, in which conserved polarity proteins are instrumental in interpreting polarity cues and generating cell asymmetry prior to cell division. We then consider how these same polarity proteins are used to polarize epithelial cells. Finally, we discuss aspects of asymmetric division in stem cells.

Polarized Membrane Traffic Allows Yeast to Grow Asymmetrically During Mating

One of the simplest and best studied forms of cell asymmetry occurs when budding yeast cells mate. As we have seen, yeast can exist in a haploid state (with a single copy of each chromosome) or a diploid state (with two copies of each chromosome). The haploid state can exist in either of two mating types ("sexes"), **a** or α. The preferred state of yeast in nature is the diploid state, so **a** cells are always looking to mate with α cells to restore the diploid state (see Figure 1-24b). Each mating type secretes a specific mating pheromone — **a** cells secrete **a** factor and α cells secrete α factor — and each cell expresses on its surface a receptor that senses the pheromone of the opposite mating type. Thus **a** cells have a receptor for α factor and α cells have a receptor for **a** factor (see Figure 16-15). When cells of opposite mating types are placed near each other, the receptors on each cell bind and detect the pheromone cue of the other cell and determine its spatially highest concentration in order to know in which direction to mate. When the cells detect the opposite mating factor, two important processes occur. First, they synchronize their cell cycles by arresting at G_0 so that when they mate, the two haploid genomes will be at the same stage of the cell cycle. Second, they target cell growth in the direction of the pheromone to assemble a mating projection called a *shmoo*. If shmooing cells of opposite

mating types touch, they fuse at the shmoo tips, and the haploid nuclei come together to restore the diploid state.

By looking for mutants in yeast haploids that cannot shmoo in response to the opposite mating pheromone, researchers have discovered how the asymmetric growth necessary for shmoo formation occurs (Figure 22-25). This mechanism initially involves a signal transduction pathway that establishes a polarized cytoskeleton, which in turn guides membrane traffic to the appropriate location for asymmetric growth. Activation of the mating-factor receptor — a typical G protein–coupled receptor (see Figures 15-12 and 16-15) — results in activation of the intrinsic polarity program, which in turn results in the localized accumulation and activation of Cdc42 in the region of the cell cortex closest to the pheromone source (Figure 22-25, step **1**). This active Cdc42·GTP leads to the local activation of a formin protein (step **2**). As we saw in Chapter 17, formin proteins nucleate the assembly of polarized actin filaments, whose (+) ends remain bound to the formin (see Figure 17-13). This process provides the tracks for the transport of secretory vesicles by a myosin V motor to the (+) ends of the filaments for localized growth and hence shmoo formation (step **3**). Notice that this mechanism requires polarity proteins, which include Cdc42·GTP, to remain concentrated at the growing shmoo tip. To ensure that polarity is maintained during shmoo growth, a directed endocytic cycle is believed to exist. In this cycle, polarity factors that have diffused away from the site of

concentration may be internalized by endocytosis and transported back to the shmoo tip, thereby reinforcing polarity (step 4).

FIGURE 22-25 Mechanism of shmoo formation in yeast. (a) The haploid yeast cell must grow toward the highest concentration of mating factor of the opposite mating type: a receptor on its surface signals the location of the highest concentration. This signal induces the localization and activation of Cdc42 to generate a higher concentration of Cdc42·GTP at this site (step 1). The Cdc42·GTP locally activates a formin, which nucleates and elongates actin filaments from this site (step 2). Because formins bind to the (+) ends of actin filaments, the (+) ends are oriented toward Cdc42·GTP and thus the highest concentration of the mating factor. A myosin V motor transports

secretory vesicles along the actin filaments, resulting in the growth of the shmoo (step 3). The polarity of the shmoo can be reinforced by an endocytic cycle that returns diffusing polarity factors back along the actin filaments to the signal site (step 4). (b) Differential interference contrast (DIC) light-microscope image of a shmooing yeast cell.

The Par Proteins Direct Cell Asymmetry in the Nematode Embryo

The nematode roundworm *Caenorhabditis elegans* has provided a powerful model system for understanding cell fate decisions (see Figure 1-23c). It was selected for study because the animal is transparent and has a rapid life cycle; it is easy to generate and characterize mutants; and the lineage of cells from the one-cell embryo to the adult is invariant (Figure 22-26a, c, d). A critical aspect of this lineage is the first cell division, in which the P0 cell — the fertilized egg, or zygote — gives rise to the AB and P1 cells by an asymmetric cell division; each of these two cells then gives rise to different lineages. Much is known about this first asymmetric division, which is where we focus our attention.

FIGURE 22-26 Cell lineage in the nematode worm *C. elegans*. (a) Pattern of the first few divisions, starting with P0 (the zygote) and leading to formation of the six founder cells (yellow highlights). The first division is asymmetric, giving rise to the AB and P1 cells. The EMS cell is so named because it gives rise to most of the endoderm and mesoderm. The P4 lineage gives rise to the cells of the germ line. (b) Micrographs of two-, four-, and eight-cell embryos. DNA is stained blue, the nuclear envelope red, and P granules green. The P1, P2, and P3 cells, which give rise to the germ line, are indicated. (c) The full lineage of the entire

body of the worm, showing some of the tissues formed. Cell division is indicated by the splitting of a line, and the time of cell division is indicated in the vertical direction. (d) Newly hatched larva. Some of the 959 somatic-cell nuclei found in the adult hermaphrodite form can be seen in this micrograph obtained by DIC microscopy.

[Part (d) republished with permission from Elsevier, from J. E. Sulston and H. R. Horvitz, 1977, "Post-Embryonic Cell Lineages of the Nematode, *Caenorhabditis elegans,*" *Devel. Biol.* **56**(1):110–156; permission conveyed through Copyright Clearance Center, Inc.]

Before the first cell division, the zygote is visibly asymmetric: cytoplasmic complexes called *P granules* are concentrated in the region of the cell that will give rise to the posterior end of the embryo (Figure 22-26b). It turns out that during further cell divisions, these P granules always segregate to cells that will give rise to the germ line, where they ultimately play an important role in germ-line development. The first asymmetric division of the P0 cell gives rise to the P1 cell, containing the P granules, and the larger AB cell. Following that, at the two-cell stage, the mitotic spindles are arranged at right angles to one another so that the ensuing cell divisions are also at right angles to one another (Figure 22-27a). To begin to understand how this first essential asymmetric division occurs, mutations in six different genes were identified that resulted in a symmetric first division. Since the P granules were not partitioned correctly in these mutants, the genes identified in this study were called *partition defective*, or *par*, genes. In these mutants, P granules did not properly localize to the posterior end of the zygote, and the mitotic spindles were not oriented correctly in preparation for the second division (see Figure 22-27a). A key insight

came when the products of the *par* genes were localized. In wild-type zygotes, many of the Par proteins localize either at the cortex of the anterior half of the cell or at the cortex of the posterior half. For example, Par3 localizes anteriorly and recruits the other components of the anterior complex comprising Par6 and aPKC (atypical protein kinase C), while Par1 and Par2 localize posteriorly (Figure 22-27b). Subsequent work has shown that mutually *antagonistic interactions* exist between these protein complexes; that is, if the Par3-Par6-aPKC complex is localized to one region, it excludes Par2, and vice versa. This is shown by the finding that the Par3-Par6-aPKC complex spreads over the whole cortex in *par2* mutants and Par2 spreads over the whole cortex in *par3* or *par6* mutants. The molecular nature of this antagonism to generate mutual exclusion is partly mediated by the protein kinase aPKC, which phosphorylates any local Par1, inhibiting its ability to bind to the anterior cortex. In a reciprocal manner, the Par1 kinase phosphorylates any local Par3 to inhibit its association with the cortex (Figure 22-26c). Additionally, the anteriorly localized Par6 now recruits Cdc42·GTP to maintain the functional polarity of the zygote, and a GTPase activating protein Cdc42-GAP that deactivates Cdc42. GTP is recruited to the posterior end to ensure that any active Cdc42·GTP is confined to the anterior end.

EXPERIMENTAL FIGURE 22-27 Par proteins are asymmetrically localized by antagonistic interactions in the one-cell worm embryo. (a) DIC images of wild-type and *par3* mutant embryos. In wild-type cells, the AB cell is larger than the P1 cell, whereas they are the same size in the *par3* mutant. The *par3* mutant also has a defect in spindle orientation (as seen by microtubule staining in green) and P-granule (red) segregation. DNA is stained blue. (b) Complementary localization of the anterior Par complex (Par3-Par6-aPKC) (red) and posterior determinants (green) in the one-cell embryo. (c) Antagonistic interactions between the anterior and posterior Par complexes. When Par3 becomes localized to the anterior it recruits the other members of the complex, Par6 and aPKC. The kinase activity of aPKC can phosphorylate local Par1, which inhibits its association with the anterior cortex. Par1 and Par2 associate with the posterior complex, and Par1 kinase can phosphorylate any Par3 to locally inhibit its association with the posterior cortex.

The unfertilized egg is symmetric, so what breaks this symmetry to generate a polarized zygote? It turns out that the position of the sperm that fertilizes the egg determines the posterior end. Prior to sperm entry, the entire egg cortex is under tension provided by an actin meshwork containing active myosin II. As we saw in Chapter

17, myosin II can form bipolar filaments that pull on actin filaments to generate tension, as is also seen in muscle and the contractile ring. Myosin II activity is regulated by a signal transduction pathway involving the small GTPase Rho (see Figure 17-42). In the unfertilized egg, Rho is maintained in its active Rho·GTP state by the uniform distribution of its activator, the guanine nucleotide exchange factor Rho-GEF. Rho·GTP activates Rho kinase, which phosphorylates the myosin light chain of myosin II to activate it (Figure 22-28a). Shortly after fertilization, the Aurora-A kinase activity associated with the sperm centrosome results in the local depletion of Rho-GEF activity. Thus the asymmetric position of the sperm centrosome defines the posterior region by local depletion of Rho·GTP, thereby lowering the activity of myosin II. With this local reduction in contractile activity, the actin-myosin network contracts toward the anterior (Figure 22-28b), and as it does so, it transports Par3 to the anterior region, where Par3 then recruits the additional components of the anterior complex (Par6 and aPKC) (Figure 22-28c). With the removal of the anterior complex, Par2 can now occupy the posterior cortex, the antagonistic interactions described above come into play, and cell asymmetry is established.

FIGURE 22-28 Mechanism of segregation of the anterior Par complex in the one-cell worm embryo. (a) Before fertilization, the cell cortex is under tension due to the activity of Rho-GEF, the guanine nucleotide exchange factor for the small GTPase Rho. Rho·GTP activates Rho kinase, which phosphorylates the regulatory light chain of myosin II to activate it. Together with actin filaments, the active myosin II maintains tension in the cell cortex. (b) Localization of myosin II before (*top*) and after (*bottom*) fertilization. The asterisk marks the

region of sperm entry. (c) Before fertilization, Rho-GEF is uniformly active, the cortex is under tension from active myosin II, and the anterior Par complex is uniformly distributed around the cortex. Upon fertilization, Rho-GEF becomes locally reduced, resulting in local deactivation of myosin II. This deactivation generates unequal tension, so the actin-myosin network contracts toward the future anterior end, moving Par3 with it, which then associates with Par6 and aPKC. Once the anterior complex is localized, factors such as Par2 associate with the posterior cell cortex.

[Part (b) republished with permission from Elsevier, from E. Munro, J. Nance, and J. R. Priess, 2004, "Cortical Flows Powered by Asymmetrical Contraction Transport PAR Proteins to Establish and Maintain Anterior-Posterior Polarity in the Early *C. elegans* Embryo," *Dev. Cell*, 2004, **7**(3):413–424; permission conveyed through Copyright Clearance Center, Inc. Part (c) Data from D. St. Johnston and J. Ahringer, 2010, *Cell* **141**:757.]

It turns out that the master regulator Cdc42 is not needed for the initial asymmetry induced by actin-myosin network contraction. However, active Cdc42·GTP binds Par6 and is necessary for maintaining the anterior complex at the anterior end. Recent work has also implicated an endocytic reinforcement cycle, as we discussed for yeast shmoo formation, to maintain polarity. Thus the steps of responding to a spatial cue, establishing asymmetry, and maintaining asymmetry are conserved features of both systems.

The Par Proteins and Other Polarity Complexes Are Involved in Epithelial-Cell Polarity

In vertebrates, polarized epithelial cells use cues from adjacent cells and the extracellular matrix to orient their axis of polarization. The process of polarization in epithelial cells of vertebrates is quite similar to that in *Drosophila*. Much of our knowledge has come from the fly system because of the ease with which mutants can be isolated and analyzed.

Genetic screens in the fly have uncovered multiple genes necessary for the generation of epithelial-cell polarity. Analyses of the proteins encoded by these genes and of the phenotypes of mutants have identified three major groups of proteins: the complex made up of Cdc42, Par3, Par6, and aPKC (in this system known as the *apical Par complex*, or simply as the *Par complex*), the Crumbs complex, and the Scribble complex. By extensive analyses of the effects of these complexes on one another when individual components are missing, a general understanding of their contributions to epithelial-cell polarization has been achieved, although a detailed molecular understanding is still emerging (Figure 22-29a).

FIGURE 22-29 Establishment of polarity in epithelial cells. (a) Polarity determination in epithelial cells is driven by an apical Par complex. The formation of a cell-cell adhesion complex induces the recruitment of the Par complex. Then, intricate and antagonistic interactions of the Par complex with both the basolateral Scribble complex and the apical Crumbs complex lead to the establishment and maintenance of epithelial-cell polarity. The localization of the different complexes to membrane domains is indicated by colored bars: the Scribble complex associates with the lateral membrane, the Par complex associates with the region at the cell junctions, and the Crumbs complex is immediately apical to the Par complex. Functional epithelial polarity is maintained by both (b) a polarized cytoskeleton and (c) membrane trafficking pathways. In the biosynthetic pathway, proteins and lipids destined for the apical and basolateral domains are sorted in the Golgi complex and transported to their respective surfaces (red arrows). Endocytic pathways (blue arrows) regulate the abundances of proteins and lipids on each surface and sort them between surfaces by transcytosis.

The first known steps in epithelial-cell polarization are interactions with the extracellular matrix and adjacent cells. The transmembrane protein b1-integrin binds to collagen in the extracellular matrix, signaling that this is the basal end of the cell. Interaction with adjacent cells in vertebrates occurs through nectin, a cell-adhesion molecule in the Ig superfamily, and a junctional protein called *JAM-A*. This induces the formation of adherens and tight junctions (see Figure 20-1) and then the apical recruitment of Par3. By Par3 interacting with other members of the apical complex — Par6 and aPKC — the Crumbs complex is recruited more apically than the Par complex, and the Scribble complex defines the basolateral surface. In the absence of the Par complex, cells cannot polarize, and, as in the nematode embryo, the Par complex is the master regulator of cell polarity. In the absence of the Scribble

complex, the apical domain is greatly expanded, whereas in the absence of Crumbs, the apical domain is greatly reduced. These observations have led to the realization that there are mutually antagonistic relationships between these complexes, in which, for example, the apical Par complex kinase aPKC antagonizes the basolateral Scribble complex by phosphorylation, and the basolaterally localized Par1 kinase antagonizes the apical Crumbs complex (see Figure 22-29a). Thus, as is the case in the nematode embryo, asymmetry is mediated by polarity complexes working antagonistically against each other.

In a manner that is only partially understood, this arrangement of polarity proteins reorganizes the cytoskeleton so that distinct arrangements of microfilaments become associated with the apical and basolateral membranes. The distribution of microtubules in epithelial cells is rather unusual, as they do not all associate with a centrosome; instead, lateral microtubules orient their (−) ends toward the apical domain and other microtubules run perpendicular to the lateral microtubules below the microvilli and also along the base of the cell (Figure 22-29b); how these arrangements are established is not known. Membrane traffic is also polarized (Figure 22-29c). Newly made membrane proteins destined for the apical and basolateral membranes are sorted and packaged into distinct transport vesicles at the *trans*-Golgi network and then transported to the appropriate surface. In addition, endocytic pathways from both the apical and basolateral surfaces regulate the abundance of

membrane proteins and transport missorted proteins using a complex set of sorting endosomes in a process known as *transcytosis*.

In genetic screens for additional components important for epithelial-cell polarity in the fly, components of endocytic trafficking were found. For example, one such mutant affects the trafficking of the apical transmembrane protein Crumbs, so that when endocytosis is compromised, the level of Crumbs on the surface goes up and the apical domain expands. Thus epithelial-cell polarity involves responses to spatial cues and reorganization of the cytoskeleton that provides a framework for both secretory and endocytic membrane traffic pathways for establishment and maintenance of the polarized state.

The Planar Cell Polarity Pathway Orients Cells Within an Epithelium

We have so far discussed asymmetry in only one dimension, but in many cases cells in multicellular organisms are polarized in at least two dimensions — top to bottom, and along a body axis. Just looking at the scales of fish, the feathers of birds, or the hairs on your arm makes it clear that the groups of cells that give rise to these structures must be organized not only in a top-to-bottom (apical/basal) manner but also in a head-to-tail, or proximal/distal,

manner. This type of polarity is called **planar cell polarity (PCP)**. A well-studied example from the fly is the single hair that points backward on each cell of the wing (Figure 22-30a). As we have seen, the fly is a model system that is particularly amenable to genetic dissection. Genetic analysis has shown that each wing cell responds to the planar direction of its neighbor, and components that specifically affect PCP have been identified (Figure 22-30b). The overall planar polarity of an epithelium is probably determined by a gradient of some ligand, such as a form of Wnt, or of mechanical tension across the tissue. This gradient polarizes all the cells in the epithelium in the same manner, causing proteins encoded by the *Frizzled* and *Dishevelled* genes to localize on one side of each cell and the proteins encoded by *Vang* and *Prickle* on the other (Figure 22-30c). Both Frizzled and Vang are transmembrane proteins, and they both associate — on opposite sides of the cell — with another membrane protein called *CELSR* (see Figure 22-30c). This asymmetric distribution of PCP proteins leads to the growth of the hair with the appropriate orientation. We have met Frizzled as a transmembrane receptor and Dishevelled as an adapter protein in the context of the Wnt pathway (see Figure 16-26), and their role in PCP may involve a form of Wnt and some other ligand. When components of the PCP pathway are disrupted — for example, in a *Dishevelled* mutant — the epithelium is intact, but the hairs are misoriented (see Figure 22-30b).

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

EXPERIMENTAL FIGURE 22-30 Planar cell polarity (PCP) determines the orientation of cells. (a) The hairs on each cell of the fly wing all point in the same direction in a wild-type fly. (b) In a fly defective in PCP, as in this *Dishevelled* mutant, the orientation of the hairs

becomes disorganized, although the cells in the epithelium are still well organized. (c) The directionality of the hair is determined by the asymmetric localization of components of the PCP pathway, as indicated for Frizzled and Dishevelled, and Vang and Prickle, all of which are needed for orienting the hair appropriately. Planar cell polarity is propagated across a tissue due to two mechanisms. First, Frizzled associated with CELSR on one cell binds to CELSR associated with Vang on the adjacent cell. Second, within each cell, the distribution of Frizzled and Vang is mutually exclusive due to antagonism between their protein complexes. (d) The sensory hair cells of the vertebrate inner ear have V-shaped arrangements of stereocilia on their surface. In the adult and 18.5-day embryo (top and center images), all the cells are oriented in precisely the same way. In a mouse Celsr1 mutant defective in PCP, the cells in the 18.5-day embryo appear normal, but their relative orientations are disrupted (arrows in bottom panel). Scale bars = 2.5 μm.

[Parts (a) and (b) reprinted with permission from John Wiley & Sons, Inc., from J. D. Axelrod and C. J. Tomlin, 2011, "Modeling the Control of Planar Cell Polarity," *Wiley Interdiscip. Rev.: Syst. Biol. Med.* **3**(5):588–605; permission conveyed through Copyright Clearance Center, Inc. Part (d) republished with permission from The Company from Biologists Ltd., from M. Fanto and H. McNeill, 2004, "Planar Polarity from Flies to Vertebrates," *J. Cell Sci*. **117**(Pt4):527–533; permission conveyed through Copyright Clearance Center, Inc.]

The complementary arrangement of PCP components means that the membrane protein Vang on the side of one cell will be adjacent to the Frizzled protein on the adjacent cell. As indicated above, each protein associates with CELSR and it is believed that CELSR can adopt two distinct states, one with Frizzled and one with Vang. Like the polarity complexes in nematodes and flies, these protein complexes show intracellular mutual antagonism (see Figure 22-30c). Thus when Frizzled on one cell is next to Vang on the adjacent cell, that adjacent cell will enrich Frizzled on its opposite side, where it will associate with Vang on the next cell, and this pattern will repeat across the tissue. In this way, complementary

interactions between complexes containing Frizzled and Vang between cells and their mutual antagonism within a cell propagate PCP across a whole tissue.

Another clear example of PCP is the sensory hair cells of the inner ear that allow vertebrates to perceive sounds. Each of these cells has an ordered array of stereocilia (actin-based structures on sensory cells in the ear, which are required for hearing — see Figure 17-20b) arranged in a V-shaped pattern, and each cell is oriented precisely like its neighbor. In a mouse with a defect in the PCP gene *Celsr1*, the orderly arrangement of stereocilia within any given cell is preserved, but the relative orientations of cells to one another are disrupted (Figure 22-30d). These types of defects can result in deafness.

The Par Proteins Are Involved in Asymmetric Division of Stem Cells

We have seen that stem cells often give rise to a daughter stem cell and a differentiated daughter cell (see Figure 22-12). What are the cues that set up these asymmetric cell divisions? Two types of mechanisms have been found (Figure 22-31). In one mechanism, cell fate determinants are segregated to one end of the cell before cell division in response to external cues. This mechanism involves the Par proteins, which, as we have already seen, are instrumental

in the first asymmetric division of the nematode embryo and in establishing epithelial-cell polarity. In the second mechanism, the stem cell divides with a reproducible orientation so that it remains associated with the stem-cell niche, whereas the daughter cell is displaced away from the niche and can then differentiate. This is the situation we have already encountered in the *Drosophila* ovary, where the cap cells form a niche for the germ-line stem cells (see Figure 22-13).

FIGURE 22-31 Two ways that stem cells can be induced to divide asymmetrically. (a) In response to an external cue, the cell polarizes and fate determinants become segregated before cell division. Division then produces one stem cell and one differentiating cell. (b) Stem cells interacting with a stem-cell niche orient their mitotic spindle to give rise to a stem cell associated with the niche and a differentiating cell displaced from it. See S. J. Morrison and J. Kimble, 2006, *Nature* **441**:1068.

A particularly well-understood example of the asymmetric division of stem cells is the formation of neurons and glial cells in the central nervous system of the fly (Figure 22-32). In this system, a neuroblast stem cell arises from the neurogenic ectoderm, which is a typical epithelial layer with apical and basal surfaces. The neuroblast enlarges (step **1**) and moves basally into the interior of the embryo but remains in contact with the neurogenic ectoderm epithelium (step **2**). It then divides asymmetrically (step **3**) to give rise to a new neuroblast and a ganglion mother cell (GMC) (step **4**). The GMC can divide only once, giving rise to two cells, either neurons or glial cells. The neuroblast, which remains a stem cell by maintaining an association with the neurogenic ectoderm niche, can divide repeatedly, giving rise to many ganglion mother cells and hence neurons and glial cells (step **5**) and thus populates the central nervous system. Thus the key event is the ability of the neuroblast to divide asymmetrically (Figure 22-32b). Once again, this process involves the asymmetric accumulation of the apical Par complex — Par3-Par6-aPKC — and its positioning at the side of the cell closest to the epithelium in an antagonistic relationship with Scribble. Par3 recruits factors that interact with the astral microtubules emanating from the spindle pole to orient the spindle — and hence cell division (Figure 22-32b). Other polarity-determining factors are then positioned at the basal side of the cell by an adaptor protein called *Miranda*, so that cell division segregates these factors (Figure 22-32c). Miranda associates with factors that

control proliferation and differentiation so they are segregated away from the neuroblast and into the GMC following cell division.

FIGURE 22-32 Neuroblasts divide asymmetrically to generate neurons and glial cells in the central nervous system. (a) Neuroblasts, which are stem cells, originate from the neurogenic ectoderm by means of signals that induce them to enlarge (step 1). They then move basally out of the ectoderm but remain in contact with it (step 2). Neuroblasts then undergo an asymmetric division (step 3) that produces a neuroblast and a ganglion mother cell (GMC) (step 4). The GMC then divides once to give two neurons or glial cells (step 5). Meanwhile, the neuroblast can divide many times to produce more GMCs, populating the neural tissue. (b) The asymmetric division of the neuroblast requires the correct orientation of the mitotic spindle, mediated by the apical Par complex and distal Miranda complex, to give rise to a larger neuroblast and a smaller GMC. (c) A neuroblast at anaphase, showing the segregation of the apical Par proteins (blue) and the basal Miranda protein (red).

The first three sections of this chapter illustrated that all metazoan organisms have evolved complex genetic proteins to ensure that, during development, the correct number of each type of differentiated cells is formed and that these cells are positioned and

polarized appropriately with respect to their neighbors. Perhaps surprisingly, many types of cells are born only to quickly die. During nematode development (see Figure 22-26a), about 15 percent of the cells that are formed are programmed to die quickly. Formation of different types of antibodies against pathogens is an essential function of the B cells of the immune system (Chapter 24), and B cells that fail to produce an antibody that targets a foreign protein also are programmed to die. In the last section of this chapter, we discuss evolutionarily conserved genetic programs that regulate cell death, and learn how these are also absolutely crucial for the formation and maintenance of many body tissues (see Figure 22-1c).

KEY CONCEPTS OF SECTION 22.3

Mechanisms of Cell Polarity and Asymmetric Cell Division

- Cell polarity involves the asymmetric distribution of proteins, lipids, and other macromolecules in the cell.
- Cells have an intrinsic program that can generate polarity using feedback loops.
- A key regulator of the polarity program in many systems is the small GTP-binding protein Cdc42.
- When a yeast cell buds, the intrinsic polarity program exploits feedback loops to concentrate Cdc42·GTP at a single site.
- Asymmetry requires cells to sense a cue, respond to it by assembling a polarized cytoskeleton, and then use this polarity to distribute polarity factors appropriately.
- Mating in haploid yeast involves assembly of a mating projection (shmoo) by polarization of the cytoskeleton in the direction of highest concentration of mating pheromone and targeting of secretion of cellular components for cell expansion there.
- Anterior/posterior asymmetry in the first division of the *C. elegans* embryo involves asymmetric contraction of the actin-myosin network to localize the anterior Par3-Par6-aPKC complex to the anterior cortex, followed by the association of posterior

factors such as Par2 with the posterior cortex. The asymmetry of the anterior and posterior complexes is maintained by mutually antagonistic pathways.

- Apical/basal epithelial-cell polarity is also driven by an apical Par3-Par6-aPKC complex, which functions in antagonistic relationships with the apical Crumbs complex and the basal Scribble complex.
- Planar cell polarity (PCP) regulates the orientation of epithelial cells across a sheet using a different set of antagonistic relationships.
- Asymmetric cell division requires that cells first become polarized, then divide to segregate fate determinants asymmetrically.
- Asymmetric division of stem cells often involves association of the stem cell with a niche, in which case the stem cell gives rise to another stem cell and a differentiating cell.
- Asymmetric stem-cell division also involves the asymmetric distribution of the Par complex, which is retained in the stem cell during division, whereas fate determinants are localized away from the Par complex to end up in the differentiating cell.

22.4 Cell Death and Its Regulation

Regulated cell death is an essential process in metazoan organisms for the removal of cells that are harmful or no longer needed. Our focus in this section will be on one principal type of programmed cell death, termed **apoptosis** — a common molecular pathway that largely is conserved in invertebrates and vertebrates. During embryogenesis, programmed apoptotic death of specific cells keeps chicken feet as well as our hands from being webbed (Figure 22-33); it also prevents our embryonic tails from persisting and our brains from being filled with unneeded nerve connections. In fact, up to 50 percent of the nerve cells generated during brain development subsequently die of apoptosis because they do not develop appropriate connections with other cells. Many kinds of muscle, epithelial, and white blood cells constantly wear out and need to be removed by apoptosis and replaced. We also discuss necroptosis, one of several types of programmed cell death that vertebrate cells employ as a response to infection or other stresses. We will see that necroptosis can lead to an immune response, which in turn can either lead to amelioration of the infection or cause inflammation and extensive tissue damage.

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

EXPERIMENTAL FIGURE 22-33 A web-footed chicken. During the development of many vertebrate limbs, cells in the soft tissue between the embryonic digits undergo programmed cell death. In the chicken foot, this process leads to the formation of four separate toes (*left*). During chicken foot development, bone morphogenetic proteins (BMPs) (members of the TGF-β superfamily of hormones; see Figure 16-22a) are expressed by interdigital cells and induce apoptosis. In this experiment, a dominant-negative type I BMP receptor was expressed in a developing chicken foot, blocking BMP signaling and preventing the programmed cell death that normally occurs. This manipulation allowed the survival of cells that then divided and differentiated into a web (*right*). The similarity of this webbing to webbed duck feet led to studies showing that BMPs are not expressed in duck interdigital cells. These results indicate that BMP signaling actively mediates cell death in the embryonic limb.

[Republished with permission from the AAAS, from H. Zou and L. Niswander, 1996, "Requirement for BMP Signaling in Interdigital Apoptosis and Scale Formation," *Science* **272**(5262):738–741; permission conveyed through Copyright Clearance Center, Inc.]

Cell-cell interactions regulate cell death in two fundamentally different ways. First, most, if not all, cells in multicellular organisms require specific protein hormone signals to stay alive. In the absence of such survival signals, frequently referred to as **trophic factors**, cells activate a *suicide program*. Second, in some developmental contexts including the immune system, and in adult life, other specific hormone signals (often on the surface of a cell) can induce the activation of a suicide program in another cell and thus *murder* the target cell. Whether cells commit suicide for lack of survival signals or are murdered by killing signals from other cells, cell death is most often mediated by apoptosis. The cell corpses are ingested by neighboring cells, and their contents are broken down into small molecules and reused to build other cells. Because there is no rupture of the plasma membrane, contents of the cell do not leak into the surrounding medium, which otherwise would lead to an inflammatory immune response.

A different form of cell death, **necrosis**, occurs when cells are subjected to injury or excessive stresses, such as heat, absence of oxygen, or infection by pathogens. Necrosis involves swelling of the cell followed by formation of holes in the plasma membrane, causing leakage of intracellular contents, which in turn attracts white blood cells, including macrophages and other phagocytic cells. In turn this leads to an inflammatory response — heat, pain, swelling — whose function is to clear out the necrotic cells and

initiate repair of the tissue. Perhaps surprisingly, necrosis can be the consequence of activating another mechanism of cellular suicide, termed **necroptosis**, which is only found in higher vertebrates. Necroptosis is often triggered by extracellular cytokines such as tumor necrosis factor alpha (TNFα). Activation of this cell-death pathway frequently causes inflammation and contributes to the development of many human diseases, including nerve degeneration and atherosclerosis.

Excess cells may also be extruded from epithelial layers, such as in gut and skin, by a mechanically regulated process that can cause detachment and the loss of trophic survival signals; extruded cells then die by yet another pathway termed *anoikis*. This maintains the epithelial barrier function as cells die and matches the rates of cell proliferation and death.

In this section, we first distinguish programmed cell death from passive cell death and then describe how genetic studies in the nematode worm *C. elegans* led to the elucidation of an evolutionarily conserved effector pathway that leads to apoptosis. We then turn to vertebrates, in which cell death is actively suppressed by trophic factors, as exemplified by their importance in programmed cell death in neuronal development, and which may be activated by pro-inflammatory cytokines and cell stresses such as DNA damage in disease conditions. We illustrate the key roles of mitochondria in initiating vertebrate cell-death pathways and describe how apoptotic

cells generate an “eat me” signal on their surface membranes. Finally, we discuss necrosis and necroptosis and how our understanding of these processes has paved the way for treating certain human diseases.

Most Programmed Cell Death Occurs Through Apoptosis

The demise of cells by programmed cell death is marked by a well-defined sequence of morphological changes, collectively referred to as *apoptosis*, a Greek word that means “dropping off” or “falling off,” like leaves from a tree. Dying cells shrink, condense, and then fragment, releasing small membrane-bound apoptotic bodies, which are then engulfed by other cells (Figure 22-34). Within these apoptotic cells, mitochondria undergo fission and lose their membrane potential, nuclei condense, and the DNA is fragmented by nuclease cleavage. Importantly, the intracellular constituents are not released into the extracellular milieu, where they could have deleterious effects by eliciting immune responses, but instead are phagocytosed by neighboring cells. The stereotypical changes that occur during apoptosis, such as condensation of the nucleus and phagocytosis by surrounding cells, suggested to early scientists that this type of cell death was under the control of a strict gene expression program. This program is critical during both embryonic and adult life to maintain normal cell number and composition.

FIGURE 22-34 Ultrastructural features of cell death by apoptosis. (a) Schematic drawings illustrating the progression of morphological changes observed in apoptotic cells. Early in apoptosis, dense chromosome condensation occurs along the nuclear periphery. The cell body also shrinks, although most organelles remain intact. Later, both the nucleus and the cytoplasm fragment, forming membrane-enveloped apoptotic bodies, which are

phagocytosed by surrounding cells without leakage of the cellular contents into the surrounding medium. (b) Photomicrographs comparing a normal HeLa cell and an apoptotic cell. Clearly visible in the latter are dense spheres of compacted chromatin as the nucleus begins to fragment.

[Part (b) T. J. Piva et al., 2012, "Increased Activity of Cell Surface Peptidases in HeLa Cells Undergoing UV-Induced Apoptosis Is Not Mediated by Caspase 3," *Int. J. Mol. Sci*. **13**(3):2650–2675; photo courtesy of Terrence Piva.]

The genes involved in controlling cell death encode proteins with three distinct functions:

- *Killer* or *initiation* proteins are required for a cell to begin the apoptotic process.
- *Destruction* proteins perform functions such as digesting proteins and DNA in a dying cell.
- *Engulfment* proteins are required for phagocytosis of the dying cell by another cell.

At first glance, engulfment seems to be simply an after-death cleanup process, but evidence indicates that it is part of the final death process. For example, mutations in killer genes always prevent cells from initiating apoptosis, whereas mutations that block engulfment genes sometimes allow cells to persist for a while before dying. Engulfment involves the assembly of a halo of actin in the engulfing cell around the dying cell or cell fragment, triggered by activation of Rac, a monomeric G protein that helps regulate actin polymerization (see Figure 17-44).

In contrast to apoptosis, cells that die by necrosis or necroptosis exhibit very different morphological changes. Cells that undergo this process swell and burst, releasing their intracellular contents, which can damage surrounding cells and frequently cause inflammation — triggering the clearance of necrotic cells and tissues damaged from the original insult and the initiation of tissue repair.

Evolutionarily Conserved Proteins Participate in the Apoptotic Pathway

The confluence of genetic studies in *C. elegans* and studies on human cancer cells suggested that an evolutionarily conserved pathway mediates apoptosis. In *C. elegans*, cell lineages are under tight genetic control and are identical in all individuals of the species. About 10 rounds of cell division or fewer create the adult worm, which is about 1 mm long and 70 μm in diameter (see Figure 22-26c). The adult worm may be a hermaphrodite (having both male and female organs) or a male. The hermaphrodite form has 959 somatic-cell nuclei, whereas the male has 1031. Scientists have traced the lineage of each somatic cell in *C. elegans* from the fertilized egg to the mature worm by following the development of live worms using DIC microscopy (see Figure 22-26d).

Of the 947 nongonadal cells generated during development of the adult hermaphrodite, 131 undergo programmed cell death. Specific

mutations revealed four genes whose encoded proteins play an essential role in controlling programmed cell death during *C. elegans* development: *ced-3, ced-4, ced-9*, and *egl-1*. In *ced-3* or *ced-4* mutants, for example, the 131 doomed cells survive (Figure 22-35). These mutants provided the first pieces of evidence that apoptosis was under a genetic program and led to the 2002 Nobel Prize for H. Robert Horvitz. The mammalian proteins that correspond most closely to the worm CED-3, CED-4, CED-9, and EGL-1 proteins are indicated in Figure 22-36. In discussing the worm proteins, we will occasionally include the mammalian names in parentheses to make it easier to keep the relationships clear.

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

EXPERIMENTAL FIGURE 22-35 Mutations in the *ced-3* gene block programmed cell death in *C. elegans*. (a) Newly hatched mutant larva carrying a mutation in the *ced-1* gene. Because mutations in this gene prevent engulfment of dead cells, highly refractile (and thus easily visualized) dead cells accumulate (arrows). (b) Newly hatched larva with mutations in both the *ced-1* and *ced-3* genes. The absence of refractile dead cells in these double mutants indicates that no cell deaths occurred. Thus the CED-3 protein is required for programmed cell death.

Cell **44**(6):817–829; permission conveyed through Copyright Clearance Center, Inc.]

FIGURE 22-36 Evolutionary conservation of apoptosis pathways. Similar proteins, shown in identical colors, play corresponding roles in nematodes and in vertebrates. (a) In nematodes, the BH3-only protein called *EGL-1* binds to CED-9 on the outer mitochondrial membrane; this interaction releases CED-4 from the CED-4/CED-9 complex. Free CED-4 then binds to and activates by autoproteolytic cleavage, the caspase CED-3, which cleaves cell proteins to drive apoptosis. These relationships are shown as a genetic pathway, with EGL-1

inhibiting CED-9, which in turn inhibits CED-4. Active CED-4 activates CED-3. (b) In vertebrates, homologs of the nematode proteins, as well as many other proteins not found in the nematode, regulate apoptosis. The Bcl-2 protein is similar to CED-9 in promoting cell survival in part by preventing activation of Apaf-1, which is similar to CED-4. Bcl-2 also prevents apoptosis by other mechanisms depicted in Figures 22-42 and 22-44. Several types of BH3-only proteins, detailed in Figures 22-41 and 22-42, inhibit Bcl-2 and thus allow apoptosis to proceed. Many apoptotic stimuli lead to damage of the outer mitochondrial membrane, causing release into the cytosol of several proteins that stimulate apoptosis. In particular, cytochrome *c* released from mitochondria activates Apaf-1, which in turn activates caspase-9, the homolog of the nematode CED-3. This initiator caspase then cleaves and thus activates effector caspase-3 and caspase-7, eventually leading to apoptosis. See text for discussion of other mammalian proteins (SMAC/DIABLO and XIAP) that have no nematode homologs.

[Information from S. J. Riedl and Y. Shi, 2004, *Nat. Rev. Mol. Cell Biol.* **5**:897.]

The first mammalian apoptotic gene to be cloned, *bcl-2*, was isolated as an oncogene from human follicular lymphomas, tumors of the antibody-producing B cells of the immune system. A mutant form of this gene was formed in a patient's lymphoma cells; a chromosomal rearrangement joined the protein-coding region of the *bcl-2* gene to an immunoglobulin-gene enhancer. The combination results in overproduction of the Bcl-2 protein, which keeps these cancer cells alive when they would otherwise become programmed to die by apoptosis. The human Bcl-2 protein and worm CED-9 protein are 23 percent identical in amino acid sequence, and the expression of a *bcl-2* transgene can block the extensive cell death observed in *ced-9* mutant worms. Thus both proteins act as regulators that suppress the apoptotic pathway (see Figure 22-36). In addition, both proteins contain a single transmembrane domain and are localized mainly to

the outer mitochondrial membrane, where they serve as sensors that control the apoptotic pathway in response to external stimuli. As we discuss next, other regulators promote apoptosis.

In the worm apoptotic pathway, CED-3 (caspase-9 in mammals) is a protease required to cleave key cell proteins during apoptosis. CED-4 (Apaf-1) is a protease-activating factor that causes autoproteolytic cleavage of the CED-3 protease to promote its activation and to initiate cell death, as CED-3 is synthesized by and present in all cells as an inactive precursor (a zymogen) (see Figures 22-36 and 22-37). Cell death does not occur in *ced-3* and *ced-4* single loss-of-function mutants or in *ced-9/ced-3* double mutants. In contrast, in *ced-9* loss-of-function mutants, all cells die by apoptosis during embryonic life, so the adult form never develops. These genetic studies indicate that CED-3 and CED-4 are killer proteins required for cell death, and that CED-9 (Bcl-2) suppresses apoptosis. The observation that all cells die in *ced-9* loss-of-function mutants shows that the apoptotic pathway is present in and can be activated in all cells. Moreover, the absence of cell death in *ced-9/ced-3* double mutants suggests that CED-9 acts upstream of CED-3 to suppress the apoptotic pathway.

FIGURE 22-37 Activation of CED-3 protease in *C. elegans*. EGL-1, a BH3-only protein that is produced in response to developmental signals that trigger cell death, displaces a CED-4 dimer from its association with CED-9 (step **1**). Four freed CED-4 dimers combine to form a CED-4 octamer (step **2**), which binds two molecules of the CED-3 zymogen (an enzymatically inactive precursor of a caspase protease). Bringing the two CED-3 zymogens together triggers the self-cleavage of the CED-3 zymogens into active CED-3 proteases (step **3**). This effector caspase then begins to cleave multiple cell proteins, leading to cell death (step **4**). See N. Yan et al., 2005, *Nature* **437**:831; and S. Qi et al., 2010, *Cell* 141:446.

The mechanism by which CED-9 (Bcl-2) controls CED-3 (caspase-9) in the nematode is known and is somewhat different from the mechanism, discussed later (see Figure 22-43), in mammalian cells. In all nematode cells the CED-9 protein, localized to the outer mitochondrial membrane, forms a complex with a dimer of the CED-4 (Apaf-1) protein, thereby preventing the CED-4 protein from activating the CED-3 protease (Figure 22-37). As a result, the cell survives. This mechanism fits with the genetics, which shows that the absence of CED-9 causes all cells in the embryo to die, but that the absence of CED-9 has no effect if CED-3 is also missing (*ced-3/ced-9* double mutants have no cell death). The three-dimensional structure of the trimeric CED-4/CED-9 complex reveals a huge contact surface between each of the two CED-4 molecules and the single CED-9 molecule; the large contact surface makes the association highly specific, but in such a way that the dissociation can be regulated.

Transcription of *egl-1*, the fourth genetically defined apoptosis regulator gene, occurs only in *C. elegans* cells that are programmed

to die. Newly produced EGL-1 protein binds to CED-9, alters its conformation, and catalyzes the release of CED-4 from CED-9 (see Figure 22-37). Both EGL-1 and CED-9 contain a 12-amino-acid sequence termed the *BH3 domain*. Because EGL-1 lacks most of the other domains of CED-9, it is called a **BH3-only protein**. The mammalian BH3-only proteins closest in sequence and function to EGL-1 are the pro-apoptotic proteins Bid and Bim, discussed later. Once EGL-1 causes dissociation of the CED-4/CED-9 complex, four released CED-4 dimers join to make an octamer, which then binds to and activates the CED-3 protease by a mechanism we will discuss shortly. Cell death soon follows (see Figure 22-37).

Evidence that the steps described here are sufficient to induce apoptosis comes from experiments in which these steps were reconstituted in vitro with purified proteins. CED-3, CED-4, a segment of the CED-9 protein that lacked its mitochondrial membrane anchor, and EGL-1 were purified, as was a CED-4/CED-9 complex. Purified CED-4 (Apaf-1) was able to bind to and accelerate the autoproteolytic cleavage and activation of purified CED-3 (caspase-9) protease, but addition of CED-9 (Bcl-2) to the reaction mixture inhibited the autocleavage. When the CED-4/CED-9 complex was mixed with CED-3, autocleavage did not occur, but addition of EGL-1 to the reaction mixture restored CED-3 autocleavage by releasing CED-4 from its complex with CED-9.

To see the importance of regulated EGL-1 expression in apoptosis, consider a class of neurons in *C. elegans* found in hermaphrodites, but not in males. These hermaphrodite-specific neurons are generated embryonically in both hermaphrodites and males but undergo programmed cell death in males. In hermaphrodites, expression of the *egl-1* gene in these neurons is repressed by the transcription factor TRA-1A, and deletion of TRA-1A in hermaphrodites causes these neurons to undergo apoptosis. This finding reinforces a point made earlier: all metazoan cells can potentially undergo apoptosis, so this process needs to be carefully regulated!

Caspases Amplify the Initial Apoptotic Signal and Destroy Key Cellular Proteins

The key enzymes that mediate apoptosis, the **caspases**, are so named because they contain a key *c*ysteine residue in the catalytic site and selectively cleave proteins at sites just C-terminal to *asp*artate residues. Caspases function as homodimers, with one domain of each stabilizing the active site of the other; they mediate apoptosis by proteolytic cleavage of selected substrates that contain their preferred cleavage sites. Their specific intracellular targets include proteins that form the nuclear lamina and cytoskeleton, whose cleavage leads to the demise of a cell. In vertebrates, targets

include other pro-apoptotic proteins such as Bid, which in turn promote mitochondrial damage. While apoptosis in *C. elegans* is executed by a single caspase CED-3, humans have 14 different caspases. In mammalian cells, apoptosis is mediated by a cascade of caspases which sequentially amplifies the initial death signal. All caspases are initially made as *procaspases* that require either binding to specific protein complexes or a proteolytic cleavage to become active.

Apoptosis of mammalian cells is activated by either intrinsic or extrinsic signaling pathways. The intrinsic apoptosis pathway is mediated by an activated *initiator caspase*, such as caspase-9, which in turn mediates the activation of the effector proteases, such as caspase-3 and caspase-7; in this way, the proteolytic activity of a few activated initiator caspases becomes rapidly and hugely amplified, leading to a massive increase in the total caspase activity level in the cell (see Figure 22-36) and consequently cell death. The extrinsic apoptosis pathway, discussed later, is initiated by ligands of death receptor family, such as TNFα (see Figure 22-44) and FasL by binding to their cognate receptors. This leads to the activation of caspase-8, an initiator caspase, which in turn activates the effector caspases, such as caspase-3 and caspase-7, to execute cell death.

Phosphatidylserine: an “Eat Me” Signal on the Surface of Apoptotic

Cells

As we learned in Section 1 of Chapter 10, the phospholipid phosphatidylserine is normally found in the inner, cytosolic leaflet of the plasma membrane. During apoptosis, increasing amounts of phosphatidylserine are found in the exoplasmic leaflet, where it acts as an "eat me" signal: it binds to several types of phosphatidylserine receptors on the surface of neighboring phagocytic cells that initiate engulfment of the cell or cell fragment. Experimentally, the presence of phosphatidylserine on the surface of a cell is indicative that it is undergoing apoptosis and can be detected by the binding of the protein annexin V (which is visualized by conjugation with a fluorescent molecule). While the normal cellular function of annexin V is obscure, it does bind tightly and specifically to phosphatidylserine.

In normal vertebrate cells, ATP-powered pumps called *ATP11A* and *ATP11C*, members of the ABC class of transmembrane proteins (see Figure 11-16), continuously transport phosphatidylserine from the outer to the inner leaflet of the plasma membrane. The phospholipid scramblases XKR8 and TMEM16F, which otherwise would translocate some of the phosphatidylserine back to the outer membrane leaflet, are inactive (Figure 22-38). During apoptosis, caspase-3 cleaves both ATP11A and ATP11C, inactivating them. Additionally, caspase-3 cleaves XKR8, and in so doing activates its function: the truncated XKR8 binds to two other proteins, dimerizes,

and becomes an active translocase, shuttling all phospholipids, including phosphatidylserine, from one leaflet of the plasma membrane to the other. The end result is appearance of the macrophage, “eat me” signal phosphatidylserine on the outer surface of the plasma membrane, where it binds to a set of receptors on the surface of macrophages and other immune system cells, triggering phagocytosis of the cell or apoptotic body (see Figure 22-34).

FIGURE 22-38 Movement of phosphatidylserine to the outer plasma membrane leaflet during apoptosis. (a) In normal vertebrate cells, ATP-powered phospholipid flippases ATP11A and ATP11C continuously translocate phosphatidylserine from the outer to the

inner leaflet of the plasma membrane (unidirectional gray arrow), and the phospholipid scramblase XKR8 which otherwise would equilibrate phosphatidylserine in both plasma membrane leaflets, is inactive. (b) In cells undergoing apoptosis, caspase-3 cleavage irreversibly inactivates ATP11A and ATP11C. In addition, caspase-3 cleaves the inactive phospholipid scramblase XKR8. The truncated XKR8, together with either basigin (BSG) or neuroplastin (NPTN), undergoes dimerization and activation, and translocates phospholipids in both directions. The end result is appearance of the "macrophage, eat me" signal phosphatidylserine on the outer surface of the plasma membrane.

Neurotrophins Promote Survival of Neurons

We noted that, in the nematode *C. elegans*, all cell lineages are under tight genetic control and are identical in all individuals of the species; during development of the adult hermaphrodite form, precisely 131 cells undergo programmed cell death. During development of vertebrates, too, many cells are born only to die, but apoptosis of most vertebrate cells is not under programmed genetic control. Rather, apoptosis is regulated by intracellular signals generated from many secreted and cell-surface protein hormones, as well as by many environmental stresses, such as ultraviolet irradiation and DNA damage. While the core apoptosis machinery in *C. elegans* is conserved in vertebrates, many other intracellular proteins also regulate apoptosis (see Figure 22-36, *right*).

Before plunging into these molecular details, we'll illustrate the importance of trophic factors in apoptosis with a brief analysis of the developing nervous system. When neurons grow to make connections to other neurons or to muscles, sometimes over considerable distances, more neurons grow than will eventually survive. As an example, the cell bodies of many sensory and motor neurons are located in the spinal cord and adjacent ganglia, while their axons grow outward from the cell body toward their target cells — often muscle cells that they will innervate (see Figure 18-55). Those neurons that make signaling connections, termed *synapses* (see Figure 23-3), with their intended target cells prevail and survive; those that fail to connect will die.

In the early 1900s, the number of neurons innervating peripheral cells was shown to depend on the size of the tissue to which they connect, the so-called *target field*. For instance, removal of limb buds from a developing chick embryo leads to a reduction in the number of both sensory and motor neurons innervating muscles in the bud (Figure 22-39). Conversely, grafting additional limb tissue to a limb bud leads to an increased number of neurons in the corresponding regions of the spinal cord and sensory ganglia. Indeed, incremental increases in target-field size are accompanied by commensurate incremental increases in the number of neurons innervating the target field. This relationship was found to result from the selective survival of neurons, rather than changes in their differentiation or proliferation. The observation that many sensory and motor

neurons die after reaching their peripheral target field suggested that these neurons compete for survival factors produced by the target tissue.

EXPERIMENTAL FIGURE 22-39 In vertebrates, the survival of motor neurons depends on the size of the muscle target field they innervate. (a) Removal of a limb bud from one side of a chick embryo at about 2.5 days of development results in a marked decrease in the number of motor neurons on the affected side. In an amputated embryo (*top*), normal numbers of motor neurons are generated on both sides of the spinal cord (*middle*) and grow outward to innervate limb muscles. Later in development, however, many fewer motor neurons remain on the side of the spinal cord with the missing limb than on the normal side (*bottom*). Note that normally only about 50 percent of the motor neurons that are generated survive. (b) Transplantation of an extra limb bud into an early chick embryo produces the opposite effect, more motor neurons on the side with additional target tissue than on the normal side. See D. Purves, 1988, *Body and Brain: A Trophic Theory of Neural Connections*, Harvard University Press.

[Data from E. R. Kandel, J. H. Schwartz, and T. M. Jessell, 2000, *Principles of Neural Science*, 4th ed., McGraw-Hill, p. 1054, Fig. 53-11.]

Subsequent to these early observations, scientists discovered that transplantation of a mouse sarcoma (muscle tumor) into a chick led to a marked increase in the local numbers of certain types of neurons. This finding implicated the tumor as a rich source of a presumed trophic factor. To isolate and purify this factor, known simply as *nerve growth factor* (NGF), scientists used cell culture assays in which outgrowth of neurites from sensory ganglia was measured. *Neurites* are extensions of the neuronal cytoplasm that can grow to become the long processes of the nervous system, the axons and dendrites (see Figure 23-1). The later discovery that the submaxillary gland of the mouse also produces large quantities of NGF enabled Rita Levi-Montalcini to purify and sequence it; she was

rewarded with a Nobel Prize. A homodimer of two 118-residue polypeptides, NGF belongs to a family of structurally and functionally related trophic factors collectively referred to as **neurotrophins**. Brain-derived neurotrophic factor (BDNF) and Neurotrophin-3 (NT-3) are also members of this protein family.

Neurotrophins bind to and activate a family of receptor tyrosine kinases called *Trks* (pronounced "tracks"). (The general structure of receptor tyrosine kinases and the intracellular signaling pathways they activate are covered in Chapter 16.) Each neurotrophin binds with high affinity to one type of Trk receptor: NGF binds to TrkA; BDNF to TrkB; and NT-3 to TrkC. NT-3 can also bind with lower affinity to both TrkA and TrkB. All neurotrophins also bind to a distinct type of receptor called $p75^{NTR}$ (also called *NTR 5 neurotrophin receptor*), but with lower affinity. $p75^{NTR}$ forms heteromeric complexes with the different Trk receptors and enhances Trk receptor signaling, much like the way the Type III TGF-β receptor enhances the binding of TGF-β to the two signaling TGF-β receptors (see Figure 16-23). These binding relationships between trophic factors and their receptors provide survival signals for different classes of neurons. As nerve axons extend outward from the spinal cord to the periphery, neurotrophins produced by their target tissues bind to Trk receptors on the growth cones (see Figure 18-55) at the tips of the extending axons, promoting survival of those neurons that successfully reach their targets.

To investigate the role of neurotrophins in development, scientists produced mice with knockout mutations in each of the neurotrophins or their receptors. These studies revealed that different neurotrophins and their corresponding receptors are required for the survival of different classes of sensory neurons (Figure 22-40). For instance, pain-sensing (nociceptive) neurons, which express TrkA, are selectively lost from the dorsal root ganglion of knockout mice lacking NGF or TrkA, whereas TrkB- and TrkC-expressing neurons are unaffected in such knockouts. In contrast, TrkC-expressing proprioceptive sensory neurons, which detect the position of the limbs, are missing from the dorsal root ganglion in *TrkC* and *NT-3* mutants.

EXPERIMENTAL FIGURE 22-40 Different classes of sensory neurons are lost in knockout mice lacking different trophic factors or their receptors. In animals lacking nerve growth

factor (NGF) or its receptor TrkA, small nociceptive (pain-sensing) neurons (light blue) that innervate the skin are missing. These neurons express the TrkA receptor and innervate NGF-producing target tissues. In animals lacking either neurotrophin-3 (NT-3) or its receptor TrkC, large proprioceptive neurons (red) innervating muscle spindles are missing. Muscle tissue produces NT-3, and the proprioceptive neurons express TrkC. Mechanoreceptors (orange; see Figure 23-33), another class of sensory neurons in the dorsal root ganglion, are unaffected in these mutants.

[Data from W. D. Snider, 1994, *Cell* **77**:627.]

Mitochondria Play a Central Role in Regulation of Apoptosis in Vertebrate Cells

As discussed previously, *C. elegans* CED-9 and its mammalian homolog Bcl-2 play central roles in regulating apoptosis. In nematodes, CED-9 does so by binding to and blocking the activation of CED-4. In vertebrates, **Bcl-2 family** members have been expanded to include Bcl-2 and Bcl-x_L that function to block apoptosis, as well as Bax and Bak that function to promote apoptosis (Figure 22-41). Bcl-2 family members either constitutively reside in the outer mitochondrial membrane or translocate to the mitochondria when induced. Bcl-2 family members primarily function to maintain (anti-apoptotic) or disrupt (pro-apoptotic) the structural integrity and low permeability of the outer mitochondrial membrane, and to prevent or induce the release of mitochondrial proteins such as cytochrome

c (see Figure 12-22) from the intermembrane space into the cytosol that in turn activate apoptotic caspases.

FIGURE 22-41 Structures of members of the Bcl-2 family of proteins. (a) The Bcl-2 family, which comprises proteins that contain functional Bcl-2 homology domains (BH1–4), can be divided into three classes. All of the pro-apoptotic and anti-apoptotic proteins, but only some of the BH3-only proteins, contain a hydrophobic and presumably transmembrane (TM) domain that may function to anchor the protein in the outer mitochondrial membrane. (b) Corresponding three-dimensional structures of representative members of each of these three classes of Bcl-2 homology domains: myeloid cell leukemia (MCL)-1; BCL-2-associated X (BAX); and p53 up-regulated modulator of apoptosis (PUMA) BH3 domain.

[Part (a) Data from Giam et al., 2009, *Oncogene* **27**:S128. Part (b) Data from M. P. A. Luna-Vargas and J. E. Chipuk, 2016, *Trends Cell Biol.* **26**(12):906.]

Before we can explain how the activity of Bcl-2 family members is regulated by trophic factors as well as by many environmental stimuli, we need to introduce several other important members of this family of proteins. All members of the Bcl-2 family share a close homology in up to four characteristic regions, termed the *B*cl-2 *h*omology domains (BH1–4; see Figure 22-41). Each of these proteins has either an anti-apoptotic or a pro-apoptotic function. All members of this family participate in oligomeric interactions; many have hydrophobic sequences at their C-termini that can anchor the proteins in the outer mitochondrial membrane.

The Pro-Apoptotic Proteins Bax and Bak Form Pores and Holes in the Outer Mitochondrial Membrane

In vertebrate cells, Bax or Bak is required for mitochondrial damage and induction of intrinsic apoptosis pathways. These two similar pro-apoptotic proteins contain three of the BH1–4 domains (see Figure 22-41) and have three-dimensional structures very similar to that of the anti-apoptotic members of the family. As evidence for the role of these proteins in promoting apoptosis, most mice lacking both Bax and Bak die in utero, and those that survive show significant developmental defects, including the persistence of interdigital webs and accumulation of extra cells in the central nervous and hematopoietic systems. Cells isolated from these mice

are resistant to virtually all apoptotic stimuli. Conversely, overproduction of Bax in cultured cells induces apoptotic death.

Bak resides in the outer mitochondrial membrane, normally tightly bound to the anti-apoptotic protein Bcl-2 or the related protein Bcl-x_L (Figure 22-42). When released from Bcl-2 — either by being present in excess, or by being displaced by the binding to Bcl-2 of certain BH3-only proteins — Bak forms large oligomers that generate pores and holes in the outer mitochondrial membrane. In healthy cells Bax is mainly cytosolic, with a small fraction shuttling to and transiently attached to the mitochondrial surface. Binding of certain pro-apoptotic proteins, discussed later, causes Bax, like Bak, to oligomerize and insert into the outer mitochondrial membrane, forming pores and holes that can be several hundreds of nanometers in diameter. Both pores and holes in the outer mitochondrial membrane allow release into the cytosol of mitochondrial proteins such as cytochrome *c* that, in normal healthy cells, are localized to the intermembrane space.

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

FIGURE 22-42 Integration of multiple signaling pathways in vertebrate cells that regulate outer mitochondrial membrane permeability and apoptosis. In healthy cells, the anti-apoptotic protein Bcl-2, or its homolog Bcl-x_L, binds to Bak and Bax pro-apoptotic proteins, blocking the ability of Bak or Bax to oligomerize and form pores in the outer mitochondrial membrane. Binding of any of several BH3-only proteins, including Bad, Bim, and Puma, directly to Bcl-2 causes Bak or Bax to dissociate from Bcl-2 and form oligomeric pores and holes in the outer mitochondrial membrane. These holes allow cytochrome *c* to enter the cytosol, where it binds to the adapter protein Apaf-1, promoting activation of caspase-9 that then initiates the apoptotic cascade and leads to cell death. Several stimuli trigger or repress this apoptotic pathway. Step 1: The presence of specific trophic factors (e.g., NGF)

leads to activation of their cognate receptor tyrosine kinases (e.g., TrkA) and activation of the PI-3 kinase–PKB (protein kinase B) pathway (see Figure 16-17). PKB phosphorylates Bad, and phosphorylated Bad then forms a complex with a cytosolic 14-3-3 protein. This Bad is sequestered in the cytosol and is unable to bind to Bcl-2. In the absence of trophic factors, nonphosphorylated Bad binds to Bcl-2, releasing Bax and Bak and allowing them to form oligomeric membrane pores and holes, activating the apoptosis pathway. Step **2**; DNA damage or ultraviolet irradiation leads to induction of synthesis of the BH3-only Puma protein. Puma binds to Bcl-2, allowing Bak and Bax to form oligomeric pores; Puma may also bind to Bak and Bax, directly activating their ability to form oligomers and permeabilize the outer mitochondrial membrane. Step **3**: Removal of a cell from its substratum disrupts integrin signaling, leading to release of the BH3-only Bim protein from the cytoskeleton. Bim also binds to Bcl-2 to promote pore formation.

[Data from D. Ren et al., 2010, *Science* **330**:1390; P. E. Czabootar et al., 2014, *Nat. Rev. Mol. Cell Biol.* **15**:49; and M. P. A. Luna-Vargas and J. E. Chipuk, 2016, *Trends Cell Biol.* **26**(12):906.]

As depicted in Figure 22-43, released cytochrome *c* activates caspase-9, predominantly by binding to and activating Apaf-1, the mammalian homolog of CED-4 (see Figures 22-36, *right* and 22-42). Binding triggers formation of an apoptosome containing seven molecules each of Apaf and cytochrome *c* — a disk-shaped 1.4-MDa heptameric wheel of death. Two of the Apaf proteins bind to domains in two procaspase-9 molecules, stimulating procaspase-9 binding to adjacent sites in the apoptosome. The conformation changes that occur upon binding trigger activation of this initiator protease; caspase-9 does not require cleavage to become activated. Caspase-9 then cleaves multiple molecules of effector caspases, such as caspase-3 (see Figures 22-36 and 22-42), leading to their activation and subsequent destruction of cell proteins and cell death. As evidence for this pathway, overproduction of Bcl-2 in cultured cells

blocks release of cytochrome *c* and apoptosis; conversely, overproduction of Bax promotes release of cytochrome *c* into the cytosol and promotes apoptosis.

FIGURE 22-43 Structure of the mammalian Apaf-1 apoptosome. Binding of cytochrome *c* to the cytosolic protein Apaf triggers formation of an apoptosome containing seven molecules each of Apaf and cytochrome *c* and having a sevenfold symmetry. The top face refers to the cytochrome *c*–exposed side of the apoptosome disk. Cytochrome *c* is colored yellow, and the several domains within each of the seven Apaf-1 protomers are color-coded. Each Apaf-1 monomer contains a caspase recruitment domain. In the heptameric apoptosome, two of these domains bind to domains in two procaspase-9 molecules, stimulating procaspase-9 binding and dimerization, and thus triggering activation of this initiator protease.

Release of SMAC/DIABLO Proteins from Mitochondria Also Promotes Caspase

Activation

In vertebrates and flies, but not in nematodes, apoptosis is regulated by several other proteins (see Figure 22-36, *right*). XIAP, one member of a family of *i*nhibitor of *a*poptosis *p*roteins (IAPs), provides another way to restrain both initiator and effector caspases. XIAP has three N-terminal BIR domains; the one termed *BIR2* binds to and inhibits two effector caspases, caspase-3 and caspase-7, while BIR3 binds to and inhibits initiator caspase-9. (Other members of the IAP family inhibit apoptosis induced by TNFα; see Figure 22-44.) The inhibition of caspases by IAPs, however, creates a problem when a cell needs to undergo apoptosis. Mitochondria enter the picture once again, since they are the source of a family of proteins, called *SMAC/DIABLOs*, that inhibit IAPs. Assembly of Bax or Bak oligomers (see Figure 22-42) leads to the release of SMAC/DIABLOs, as well as cytochrome *c*, from the mitochondrial intermembrane space. SMAC/DIABLOs then bind to XIAP in the cytosol, thereby blocking XIAP from binding to caspases. By relieving XIAP-mediated inhibition, SMAC/DIABLOs promote caspase activity and cell death.

FIGURE 22-44 Cell murder: the extrinsic apoptosis and necroptosis pathways. (a) Extrinsic (or death receptor–regulated) apoptosis pathways are found in many types of cells, which may be activated by Fas, TNFα, and other members of the TNFα family of proteins. For example, binding of TNFα on the surface of one cell to the TNFα death receptor on an adjacent cell leads to the binding of two cytosolic death domain (DD)-containing proteins, the adapter protein TRADD (TNF receptor-associated DD protein) and receptor-interacting-protein 1 (RIPK1), to the DD on the intracellular segment of TNFα receptor 1, leading to the formation of a large intracellular signaling complex. FADD (Fas-associated DD protein) can then bind, leading to the binding, dimerization, and proteolytic activation of the initiator caspase-8. Active caspase-8 then cleaves and activates effector caspases 3, 6, and 7, which cleave vital cellular proteins and induce cell death. Cleavage of the BH3-only protein Bid (BH3-interacting-domain death agonist) by caspase-8 generates the tBid fragment that binds to Bcl-2 on the outer mitochondrial membrane, leading to release of Bad or Bax followed by their oligomerization and pore formation in the outer mitochondrial membrane, release of cytochrome *c* into the cytosol, and activation of the intrinsic apoptosis pathway (see Figure 22-41) as well. RIPK1 is an essential kinase and adaptor in the apoptosis and necroptosis pathway; it contains an N-terminal kinase domain and a RHIM domain. When the decision is to die by apoptosis, RIPK1 binds to FADDs, as above leading to the binding,

dimerization, and proteolytic activation of the initiator caspase-8. (b) When apoptosis fails to be activated, for example in the absence of caspase-8 or FADD, the necroptosis pathway can be activated, triggered by activation of RIPK1 kinase. Step **1**: Activated RIPK1 forms multiprotein complexes via its RHIM domain with the kinase RIPK3, and RIPK3 becomes activated by phosphorylation of a residue in its activation loop. Step **2**: Active RIPK3 then binds to the kinase-like domain of the MLKL protein and phosphorylates it. Step **3**: This induces a conformational change in MLKL that (step **4**) enables it to form oligomers that insert into the plasma membrane. Either directly by forming ion channels or indirectly by interacting with other plasma membrane proteins this destabilizes the integrity of the plasma membrane, inducing cell swelling and rupture. See P. Bouillet and L. A. O'Reilly, 2009, *Nat. Rev. Immunol.* **9**:514; A. Ashkenazi and G. Salvesen, 2014, *Annu. Rev. Cell Dev. Bi.* **30**:337; Y. Dondelinger et al., 2016, *Trends Cell Biol.* **26**:721, https://doi.org/10.1016/j.tcb.2016.06.004; and B. Shan et al., 2018, *Genes Dev.* **32**:327, https://doi.org/10.1101/gad.312561.118.

Trophic Factors Induce Inactivation of Bad, a Pro-apoptotic BH3-Only Protein

We saw earlier that neurotrophins such as NGF protect neurons from cell death; this effect is mediated by inactivation of a pro-apoptotic BH3-only protein called *Bad*. In the absence of trophic factors, Bad is nonphosphorylated and binds to Bcl-2, or to the closely related anti-apoptotic protein Bcl-x_L, at the outer mitochondrial membrane (see Figure 22-42). This binding inhibits the ability of Bcl-2 and Bcl-x_L to bind Bax and Bak, thereby allowing Bak and Bax to oligomerize in the plane of the outer mitochondrial membrane and form pores and holes in it, triggering release of cytochrome *c* and induction of apoptosis.

A number of trophic factors, including NGF, induce the PI-3 kinase signaling pathway, leading to the activation of protein kinase B (see Figure 16-17). Activated protein kinase B phosphorylates Bad; phosphorylated Bad cannot bind to Bcl-2 or Bcl-x_L and is found in the cytosol complexed to the phosphoserine-binding protein 14-3-3 (see Figure 16-13). As evidence for this pathway, a constitutively active form of protein kinase B can rescue cultured neurotrophin-deprived neurons, which would otherwise undergo apoptosis and die. These findings support the mechanism for the survival action of trophic factors depicted in Figure 22-42. In other cell types, different trophic factors promote cell survival through post-translational modification of other components of the cell-death machinery.

Apoptosis in Vertebrates Is Induced by BH3-Only Pro-apoptotic Proteins That Are Activated by Environmental Stresses

Whereas nematodes contain a single BH3-only protein, EGL-1, mammals express at least eight, including Bad, in a cell type- and stress-specific manner. The pro-apoptotic activities of these proteins are tightly regulated by diverse transcriptional and post-transcriptional mechanisms. Two BH3-only proteins, Puma and the related protein Noxa (see Figure 22-42), are transcriptionally induced by the p53 protein (see Figures 19-32 and 19-34); they

induce apoptosis primarily by binding to and inactivating the anti-apoptotic Bcl-2 and Bcl-x_L proteins, thus promoting the polymerization and pore formation of pro-apoptotic Bcl-2 family members Bax and Bak. This interaction is part of the checkpoint pathway by which unrepaired damage to DNA can induce apoptosis; thus the loss of p53 seen in many cancers allows cells to live with severe DNA damage (see Figure 25-23). Another BH3-only protein, Bim, is normally sequestered by the microtubule cytoskeleton by binding to a dynein light chain (see Chapter 18). Detachment of cells from their substratum disrupts integrin signaling, rearranges the cytoskeleton, and leads to release of Bim. Like Puma, Bim binds directly to Bcl-2, releasing Bak and Bax from Bcl-2 and allowing formation of pores and holes in the outer mitochondrial membrane (see Figure 22-42). Thus apoptosis of mammalian cells is regulated by a careful balance of activities of anti-apoptotic proteins such as Bcl-2 and Bcl-x_L and multiple pro-apoptotic BH3-only proteins.

Apoptosis and Necroptosis Can Be Triggered by Tumor Necrosis Factor, Fas Ligand, and Related Death Proteins

Although cell death can arise as a default in the absence of survival factors, apoptosis can also be stimulated by positively acting death signals that activate the extrinsic apoptosis pathway; the extrinsic

pathway activated by death ligands can also activate the alternative programmed cell death pathway termed *necroptosis*. Murder of infected cells is an effective means of stemming the spread of a pathogen throughout an organism. To that end macrophages and other immune system cells are recruited to sites of infection, where they become activated and produce cytokines such as tumor necrosis factor alpha (TNFα) that can remain attached to the cell surface or be cleaved off and function as a secreted hormone. TNFα, in turn, triggers the death of adjacent cells that might have been infected. However, overproduction of TNFα can lead to the tissue destruction seen in certain chronic inflammatory diseases (see Chapter 24). Another important death-inducing signal, the Fas ligand, is a cell-surface protein produced by activated natural killer cells and cytotoxic T lymphocytes. By binding to the Fas protein on target cells, this signal can trigger death of virus-infected cells, some tumor cells, and foreign graft cells. Depending on the type of cell and infection, death can be by apoptosis or by necroptosis (discussed later in this section).

Both TNFα, depicted in Figure 22-44, and the Fas ligand (also called *CD95 ligand*) are trimeric proteins present on the surface of one cell that bind to *death receptors* on an adjacent cell. Each of these death receptors has an extracellular domain that binds to its cognate ligand, a single transmembrane domain, and an intracellular protein-protein interaction domain known as a *death domain (DD),* which is why they are called *death receptors*. These receptors are

activated when binding of a trimeric ligand brings the receptor molecules into close proximity to allow the formation of an intracellular complex that recruits downstream signaling molecules, similar to the formation of the interleukin 1 signalsome (see Figure 16-31). We will use TNFα, a highly pro-inflammatory cytokine involved in mediating a myriad of human diseases, as an example.

Binding of TNFα to the TNF receptor 1 (TNFR1), a DD-containing death receptor, leads to the formation of an intracellular signaling complex which is initiated by the recruitment of another two DD-containing signaling molecules, *T*NF *r*eceptor-*a*ssociated *d*eath *d*omain protein (TRADD) and *r*eceptor-*i*nteracting *p*rotein *k*inase 1 (RIPK1) (Figure 22-44a). TRADD and RIPK1 in turn recruit a large signaling complex, not depicted in the figure, including E3 ubiquitin ligases, deubiquitinating enzymes, and kinases, which collectively decides, within a few minutes, whether the cell should activate NF-κB to survive, or die by apoptosis or necroptosis.

The activation of RIPK1 kinase is a key decisive event that can initiate cell death by either apoptosis or necroptosis. Activated RIPK1 can bind to FADD, which then serves as an adapter to recruit and activate caspase-8, an initiator caspase (Figure 22-44a). FADD can also be directly activated by binding to TRADD in RIPK1-independent apoptosis activation. Like the other initiator caspase, caspase-9, caspase-8 is activated by dimerization following binding of two molecules to the FADD proteins recruited to an active death

receptor trimer. Once activated, caspase-8 cleaves and thus activates several effector caspases which then cleave many cellular proteins to complete apoptotic cell death.

Caspase-8 also cleaves the BH3-only protein *B*H3-*i*nteracting-domain *d*eath agonist (Bid). The resulting tBid fragment (but not the full-length Bid) then binds to Bcl-2 on the outer mitochondrial membrane, leading to the dissociation of Bik and Bax and formation of Bak/Bax pores and holes, release of cytochrome *c* into the cytosol, and activation of the intrinsic apoptosis pathway (see Figure 22-42) as well.

Necroptosis, a genetically programmed type of necrosis, is a well-defined defense mechanism against certain viruses. As part of their replication cycle, many viruses produce an inhibitor of caspase-8, a key component of the TNFα cell murder pathway depicted in Figure 22-44a, thus preventing apoptosis and allowing continued replication of the virus and spread of the infection to neighboring cells. In cells lacking functional caspase-8, TNFα triggers an alternative pathway, necroptosis. In this pathway, activated RIPK1 binds to RIPK3, a family member of RIPK1, promoting activation of RIPK3 and triggering necroptosis. In this process, activated RIPK3 in turn phosphorylates another essential protein termed *MLKL*. Phosphorylation causes MLKL to alter its conformation and form oligomers that insert into the plasma membrane and form holes, allowing Ca^{2+} entry. The influx of Ca^{2+} causes the cell and its

organelles to swell and burst, releasing its contents into the extracellular space. Some of the released intracellular proteins trigger activation of immune-system cells and cause tissue inflammation and damage. Inflammation due to necroptosis has been implicated in mediating major human inflammatory diseases, including rheumatoid arthritis, inflammatory bowel disease, neurodegenerative diseases such as amyotrophic lateral sclerosis and Alzheimer's disease and progressive atherosclerotic lesions.

As we discussed in Chapter 16, protein inhibitors of TNFα are among the most widely used therapeutics for many inflammatory diseases; inhibiting RIPK1 kinase is another promising approach to treating human diseases characterized by necrosis and inflammation. Recall that TNFα activates multiple signal transduction pathways: one leads to activation of the transcription factor NF-κB (see Figure 16-30), a second to apoptosis, and the third to necroptosis (see Figure 22-44). Much work needs to be done to understand the regulation of each of these pathways and their interactions, as this cytokine is involved in many inflammatory diseases.

KEY CONCEPTS OF SECTION 22.4

Cell Death and Its Regulation

- All vertebrate cells require trophic factors to survive. In the absence of these factors, cells commit suicide.
- Genetic studies in *C. elegans* have defined an evolutionarily conserved apoptotic pathway with three major components: membrane-bound regulatory proteins,

cytosolic regulatory proteins, and apoptotic proteases (called *caspases* in vertebrates) (see Figure 22-36).

- Once activated, caspases cleave specific intracellular substrates, leading to the demise of a cell. Other proteins (e.g., CED-4, Apaf-1) that bind regulatory proteins and caspases are required for caspase activation (see Figures 22-36, 22-37, and 22-43).
- Survival of motor and sensory neurons during development is mediated by neurotrophins released from target tissues that bind to Trk receptor tyrosine kinases on the neuronal growth cones (see Figure 22-40), activating an anti-apoptotic response via the PI-3 kinase pathway (see Figure 22-42).
- The Bcl-2 family contains both pro-apoptotic and anti-apoptotic proteins; most are transmembrane proteins and engage in protein-protein interactions.
- In mammals, apoptosis can be triggered by oligomerization of Bax or Bak proteins in the outer mitochondrial membrane, leading to efflux of cytochrome *c* and SMAC/DIABLO proteins into the cytosol; these proteins then promote caspase activation and cell death.
- Bcl-2 proteins can restrain the oligomerization of Bax and Bak, inhibiting cell death.
- Pro-apoptotic BH3-only proteins (e.g., Puma, Bad) are activated by environmental stresses and stimulate the oligomerization of Bax and Bak, allowing cytochrome *c* to escape into the cytosol, bind to Apaf-1, and thus activate caspases.
- Direct interactions between pro-apoptotic and anti-apoptotic proteins lead to cell death in the absence of trophic factors. Binding of extracellular trophic factors can trigger changes in these interactions, resulting in cell survival (see Figure 22-42).
- Binding of extracellular death signals, such as tumor necrosis factor and Fas ligand, to their receptors oligomerizes an associated protein (FADD), which in turn triggers the caspase cascade, leading to cell murder by apoptosis (see Figure 22-44a).
- In the presence of inhibitors of caspase-8, tumor necrosis factor induces necroptosis (Figure 22-44b). Intracellular proteins released into the surroundings as a result can cause inflammation and tissue damage.

Key Terms

apoptosis
asymmetric cell division
Bcl-2 family
BH3-only protein
blastocyst
caspases
cell lineage
cytokine
embryonic stem (ES) cell
germ line
induced pluripotent stem (iPS) cell
inner cell mass (ICM)
meristem

multipotent
necroptosis
necrosis
neoblast
neurotrophins
planar cell polarity (PCP)
pluripotent
polarity
progenitor (precursor) cell
programmed cell death
somatic cell
stem cell
stem-cell niche
symmetric cell division
totipotent
trophectoderm (TE)
trophic factor

Review the Concepts

1. What two properties define a stem cell? Distinguish between a totipotent stem cell, a pluripotent stem cell, and a precursor (progenitor) cell.
2. Where are stem cells located in plants? Where are stem cells located in adult animals? How does the concept of a stem cell differ between animal and plant systems?

3. In 1997, Dolly the sheep was cloned by a technique called *somatic-cell nuclear transfer* (or *nuclear-transfer cloning*). A nucleus from an adult mammary cell was transferred into an egg from which the nucleus had been removed. The egg was allowed to divide several times in culture, then the embryo was transferred to a surrogate mother who gave birth to Dolly. Dolly died in 2003 after mating and giving birth herself to viable offspring. What does the creation of Dolly tell us about the potential of nuclear material derived from a fully differentiated adult cell? Does the creation of Dolly tell us anything about the potential of an intact, fully differentiated adult cell?
4. Identify whether the following contain totipotent, pluripotent, or multipotent cells: (a) inner cell mass, (b) morula, (c) eight-cell embryo, (d) trophectoderm.
5. True or false: Differentiated somatic cells have the capacity to become reprogrammed to become other cell types. Provide one line of evidence discussed in the chapter that corroborates your response.
6. Explain how intestinal stem cells were first identified and then experimentally shown to be multipotent stem cells.
7. Explain how hematopoietic stem cells were experimentally shown to be both multipotent and capable of self-renewal.
8. The nematode *C. elegans* has proved to be a valuable model organism for studies of cell birth, cell asymmetry, and cell death. What properties of *C. elegans* render it so well suited for these studies? Why is so much information from *C.*

elegans experiments of use to investigators interested in mammalian development?

9. Asymmetric cell division often relies on cytoskeletal elements to generate or maintain the asymmetric distribution of cellular factors. In *Saccharomyces cerevisiae*, what factor is localized to the bud by myosin motors? In *Drosophila* neuroblasts, what factors are localized apically by microtubules?
10. Discuss the role of *par* genes in generating anterior/posterior polarity in the *C. elegans* embryo.
11. How do studies of nerve and muscle development in knockout mice support the statement that apoptosis is a default pathway in neuronal cells?
12. Compare and contrast cell death by apoptosis and by necrosis.
13. Identify and list the functions of the three general classes of proteins that control cell death.
14. Based on your understanding of the events surrounding cell death, predict the effect(s) of the following on the ability of a cell to undergo apoptosis:
    a. Functional CED-9; nonfunctional CED-3
    b. Active Bax and cytochrome *c*; nonfunctional caspase-9
    c. Inactive PI-3 kinase; active Bad
15. TNF and Fas ligand bind cell-surface receptors to trigger cell death. Although the death signal is generated external to the cell, why do we consider the death induced by these molecules to be apoptotic rather than necrotic?

16. Predict the effects of the following mutations on the ability of a cell to undergo apoptosis:
    a. Mutation in Bad such that it cannot be phosphorylated by protein kinase B (PKB)
    b. Overexpression of Bcl-2
    c. Mutation in Bax such that it cannot form homodimers

    One common characteristic of cancer cells is a loss of function in the apoptotic pathway. Which of the mutations listed above might you expect to find in some cancer cells?
17. How do IAPs (inhibitors of apoptosis proteins) interact with caspases to prevent apoptosis? How do mitochondrial proteins interact with IAPs to prevent inhibition of apoptosis?

CHAPTER 23

Cells of the Nervous System

Luis de la Torre-Ubieta, Geschwind Laboratory, UCLA.
Lodish et al., *Molecular Cell Biology*, 9e, © 2021
W. H. Freeman and Company

Coronal slice of CLARITY-treated adult mouse brain expressing green fluorescent protein (GFP) in a subset of neurons (Thy1-GFP). CLARITY renders tissue optically transparent, permitting deep and complete imaging of tissues. Each section was stained with antibodies to GFP and color coded by depth to facilitate individual neuron visualization. This approach provides unprecedented opportunity to image intact brains at cellular resolution, paving the way to a comprehensive understanding of how the brain is wired.

OUTLINE

23.1 Neurons and Glia: Building Blocks of the Nervous System
23.2 Voltage-Gated Ion Channels and the Propagation of Action Potentials
23.3 Communication at Synapses
23.4 Sensing the Environment: Touch, Pain, Taste, and Smell

The nervous system, which consists of the central (brain and spinal cord) and peripheral (nerves outside of the brain and spinal cord) nervous systems, regulates all aspects of bodily function and is staggering in its complexity. The 1.3 kg adult human brain — the control center that stores, computes, integrates, and transmits information — contains nearly 100 billion nerve cells, called *neurons*. These neurons are interconnected by some 100 trillion synapses, the junction points where two or more neurons communicate. An individual neuron can form synapses with up to 10,000 other neurons.

Neurons are organized into interconnected units or circuits that have discrete functions. Some circuits sense features of both the external and internal environments of organisms and transmit this information to the brain for processing and storage. Others regulate the contraction of muscles and the secretion of hormones. Yet other circuits regulate cognition, emotion, and innate as well as learned behaviors. In addition to neurons, the nervous system contains glial cells. Historically considered to function simply as support cells for neurons, it is now recognized that glia play active roles in brain function.

The biology of the cells of the nervous system is remarkable on two levels. First, neurons are the most morphologically polarized and

compartmentalized cells in the body; their unique morphology is supported by remarkable cell biological processes, from cytoskeletal dynamics and membrane trafficking to signal transduction and activity-dependent gene regulation. Second, individual neurons and glia combine to form exquisitely complex and precise networks or circuits. Neural circuits are not completely hardwired; instead, the connectivity of neurons changes with experience through a process known as *synaptic plasticity*, in which experience modifies the strength and number of synaptic connections between neurons. A central focus of modern brain biology is to understand the logic underlying both the formation and the plasticity of neural circuits. While the structure and function of nerve cells is understood in great detail, the mechanisms by which neural circuits form, change with experience, and process and compute information remain a mystery. These issues represent some of the most exciting areas of twenty-first-century biology and inspired President Obama to launch the Brain Research through Advancing Innovative Neurotechnologies (BRAIN) Initiative in 2013. One major aim of this ongoing, large-scale national effort is to catalogue and characterize the extraordinary diversity of cell types in the brain and to understand the logic by which these cells form circuits that underlie brain functions.

The vertebrate nervous system is anatomically divided into the central nervous system, which contains the nerves and glia located inside the brain and spinal cord, and the peripheral nervous system,

which contains the nerves and glia located outside the brain and spinal cord. Despite being anatomically separate, the central and peripheral nervous systems are functionally interconnected, with peripheral nerves serving as communication conduits between the brain and the body. The central nervous system itself can be divided into four primary components: the spinal cord, brain stem, cerebellum, and cerebrum (Figure 23-1a). Each region has discrete functions. The spinal cord conducts sensory and motor information from the body to the brain, the brain stem regulates basic functions such as breathing and blood pressure, the cerebellum controls motor function, and the cerebrum processes motor and sensory information, language, learning and memory, and other higher level functions. These primary components are further divided into distinct functional areas; for example, the cerebrum is organized into distinct frontal, temporal, parietal, and occipital lobes, each of which is involved in specific, though partially overlapping, functions (Figure 23-1b). Although there are neurons and glia that have distinct properties and characteristics specific to these various regions, the functional specialization of each brain region emerges primarily from differences in circuit connectivity rather than from differences in constituent cell types.

FIGURE 23-1 Major areas of the mammalian central nervous system and typical morphology of two types of mammalian neurons. (a) The mammalian central nervous system is composed of four major areas: the spinal cord, which relays sensory and motor information from the body to the brain; the brain stem, which controls many basic functions such as breathing and heart rate; the cerebellum, which coordinates movements; and the cerebrum, which controls higher functions such as language, learning, memory and emotion. (b) The mammalian cerebrum consists of four lobes, each of which mediates specific, partially overlapping functions. The lobes are: the frontal lobe, involved in executive functions such as problem solving, language, and impulse-control; the temporal lobe, involved in auditory processing, memory, and emotion; the parietal lobe, involved in touch, taste, temperature, and movement sensations; and the occipital lobe, involved primarily in vision. (c) A multipolar interneuron has profusely branched dendrites, which receive signals at synapses from several hundred other neurons. Small voltage changes imparted by inputs in the dendrites can sum to give rise to the more massive action potential, which starts in the hillock. A single, long axon that branches laterally at its terminus transmits signals to other neurons. (d) A motor neuron innervating a muscle cell typically has a single, long axon extending from the cell body to the effector cell. In

mammalian motor neurons, an insulating sheath of myelin usually covers all parts of the axon except at the nodes of Ranvier and the axon termini. The myelin sheath is composed of cells called *oligodendrocytes* in the central nervous system and Schwann cells in the peripheral nervous systems, both of which are glial cells (see Figure 23-18).

Indeed, despite the multiple types and shapes of neurons that are found in metazoan organisms, all nerve cells share common properties that make them specialized for communicating information using a combination of electrical and chemical signaling, as we will see in more detail in the next section. *Electrical signals* conduct information within neurons, which are usually highly polarized cells with extensions whose lengths are orders of magnitude greater than the cell soma (Figure 23-1c and d). The electrical pulses that travel along neurons are called *action potentials,* and information is encoded as the frequency at which action potentials are fired. Owing to the speed of electrical transmission, neurons are champion signal transducers, much faster than cells that secrete hormones. In contrast to the electrical signals that conduct information within a neuron, *chemical signals* transmit information between cells, utilizing processes similar to those employed by other types of signaling cells (see Chapters 15 and 16).

Taken together, the electrical and chemical signaling of the nervous system allows it to detect external stimuli, integrate and process the information received, relay it to higher brain centers, and generate an appropriate response to the stimulus. For example, **sensory**

neurons have specialized receptors that convert diverse types of stimuli from the environment (e.g., light, touch, sound, odorants) into electrical signals. These electrical signals are then converted into chemical signals that are passed on to other cells called **interneurons,** which convert the information back into electrical signals. In some circuits, this information is then transmitted to muscle-stimulating **motor neurons** or to other neurons that stimulate other types of cells, such as glands (an example of this type of simple neural circuit is shown in Figure 23-4).

In this chapter, we will focus on neurobiology at the cellular and molecular level. We will start by looking at the general architecture of neurons, at how they carry signals, and at how neurons and glia arise from stem cells. Next we will focus on ion flow, channel proteins, and membrane properties: how electrical pulses move rapidly along neurons. Third, we will examine communication between neurons where electrical signals traveling along a cell are translated into a chemical pulse between cells and then back into an electrical signal in the receiving cells. We will then examine neurons in several sensory tissues, including those that mediate our senses of touch, taste, and olfaction. The speed, precision, and integrative power of neural signaling enable the accurate and timely sensory perception of a swiftly changing environment. In the last section, we will turn to the circuits, neurons, and cell biological mechanisms underlying the storage of memories.

A great deal of information about nerve cells has been gleaned from analyses of humans, mice, nematodes, and flies bearing mutations that affect specific functions of the nervous system. In addition, molecular cloning and structural analysis of key neuronal proteins, such as voltage-gated ion channels and receptors, have helped elucidate the cellular machinery underlying complex brain functions such as instinct, learning, memory, and emotion. We will be referring to these model organisms and methodologies throughout this chapter.

23.1 Neurons and Glia: Building Blocks of the Nervous System

In this section, we examine the structure of neurons and connect this structure to the function of these cells. **Neurons** are distinguished by their elongated, asymmetric shape, by their highly localized proteins and organelles, and most of all by channel proteins that controls the flow of ions across the plasma membrane. Specific properties of neurons also give the nervous system considerable powers of signal analysis. One neuron can respond to the inputs from multiple neurons, generate electrical signals, and transmit the signals to multiple neurons. For example, a neuron might transmit a signal only if it receives five simultaneous activating signals from input neurons. The receiving neuron measures both the amount of incoming signal and whether the five signals are roughly *synchronous*. Fast synaptic input from one neuron to another can be either *excitatory* — combining with other signals to trigger electrical transduction in the receiving cell — or *inhibitory*, discouraging such transmission. In addition to excitatory and inhibitory synapses, neurons receive slower *neuromodulatory* inputs such as norepinephrine, dopamine, serotonin, and acetylcholine, which activate G protein–coupled receptors (see Chapter 15) to change the threshold for excitation or inhibition. Thus the properties and connections of individual neurons set the stage for integration and refinement of information. The output of a

nervous system is the result of its circuit properties, that is, the wiring or interconnections between neurons and the strength of these interconnections. We will begin by looking at how signals are received and sent, and in subsequent parts of the chapter we will look at the molecular details of the machinery involved.

Information Flows Through Neurons from Dendrites to Axons

Neurons arise from roughly spherical *neuroblast* precursors. Newly born neurons can migrate long distances before growing into dramatically elongated cells. Fully differentiated neurons take many forms, but generally share certain key features (see Figure 23-1c and d). The nucleus is found in a rounded part of the cell called the *cell body*. Branching cell processes called **dendrites** (from the Greek for "treelike") are found at one end and are the main structures where signals are received from other neurons via synapses. Incoming signals are also received at synapses that form on neuronal cell bodies. Neurons often have extremely long dendrites with complex branches, particularly in the central nervous system (i.e., the brain and spinal cord). This allows them to form synapses with, and receive signals from, a large number of other neurons — up to tens of thousands. Thus the converging dendritic branches allow signals from many cells to be received and integrated by a single neuron.

When a neuron is first differentiating, the end of the cell opposite the dendrites undergoes dramatic outgrowth to form a long, extended arm called the **axon**, a structure that essentially acts as a transmission wire. The growth of axons must be controlled so that proper connections are formed; this is accomplished through a complex process called *axon guidance* that involves dynamic changes to the cytoskeleton (see Section 18.8). The diameters of axons vary from just a micrometer in certain neurons of the human brain to a millimeter in the giant axon of the squid. Axons can be meters in length (e.g., in giraffe necks) and are often partly covered with electrical insulation called the **myelin sheath** (see Figure 23-1d), which is made by specific classes of glial cells: oligodendrocytes (in the central nervous system) and Schwann cells (in the peripheral nervous system). The insulation speeds electrical transmission. The short, branched ends of the axon at the opposite end of the neuron from the dendrites are called the *axon termini.* This is where signals are passed along to the next neuron or to another type of cell, such as a muscle or hormone-secreting cell. The asymmetry of the neuron, with dendrites at one end and axon termini at the other, is indicative of the primarily unidirectional flow of information from dendrites to axons.

Information Moves Along Axons as Pulses of Ion Flow Called *Action Potentials*

Nerve cells are members of a class of *excitable cells,* which also includes muscle cells, cells in the pancreas, and some others. Like all metazoan cells, excitable cells have an inside-negative voltage or electric potential gradient across their plasma membranes, the **membrane potential** (see Chapter 11). Unlike other cells, neurons can use their unique electrical properties to send signals. The signals take the form of brief local voltage changes, from inside-negative to inside-positive, an event designated **depolarization**. A powerful surge of depolarizing voltage change, moving from one end of the neuron to the other, is called an **action potential**. A recording of several depolarization events, with the neuron going from inside-negative to neutral to inside-positive, is shown in Figure 23-2. At the peak of an action potential, the membrane potential can be as much as +50 mV (inside-positive), a net change of ~120 mV. As we will see in greater detail in Section 23.2, an action potential moves along the axon to the axon terminus at speeds of up to 100 meters per second. In humans, for instance, axons may be more than a meter long, yet it takes only a few milliseconds for an action potential to move along their length. Neurons can fire repeatedly after a brief recovery period, for example, every 4 milliseconds (ms), as in Figure 23-2. After the action potential passes through a section of a neuron, channel proteins and pumps restore the inside-negative resting potential (**repolarization**). The restoration process chases the action potential down the axon to the terminus, leaving the neuron ready to signal again.

EXPERIMENTAL FIGURE 23-2 Recording of an axonal membrane potential over time reveals the amplitude and frequency of action potentials. An action potential is a sudden, transient depolarization of the membrane, followed by repolarization to the resting potential of about −70 mV. The axonal membrane potential can be measured with a small electrode placed into it (see Figure 11-19). This recording shows the neuron generating one action potential about every 4 milliseconds.

Action potentials are all or none. Once the threshold to start one is reached, a full firing occurs. The signal information is therefore carried primarily not by the intensity of the action potentials but by their timing and frequency. The stronger the stimulus, the higher the frequency of action potential firing.

As previously mentioned, neurons are not the only excitable cells in the body. Muscle contraction is triggered by motor neurons that

synapse directly on excitable muscle cells (see Figure 23-1d). Insulin secretion from the β islet cells of the pancreas is triggered by neurons. In both cases, the activating event involves an opening of plasma membrane channels that causes changes in the transmembrane flow of ions and in the electrical properties of the regulated, non-neuronal cells.

Information Flows Between Neurons via Synapses

How is information communicated between neurons? Axon termini from one neuron are closely apposed to dendrites of another, at junctions called *chemical synapses* or simply **synapses** (Figure 23-3). The axon terminus of the *presynaptic cell* contains many small vesicles, termed **synaptic vesicles**, each of which is filled with a single kind of small molecule known as a **neurotransmitter**. Arrival of an action potential at a presynaptic terminus causes an influx of calcium that triggers exocytosis of a small number of synaptic vesicles, releasing their content of neurotransmitter molecules.

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

FIGURE 23-3 A chemical synapse. (a) A narrow region, the synaptic cleft, separates the plasma membranes of the presynaptic and postsynaptic cells. Arrival of action potentials in a presynaptic cell causes exocytosis at a synapse of a small number of synaptic vesicles, releasing their content of neurotransmitters (red circles). Following their diffusion across the synaptic

cleft, the neurotransmitters bind to specific receptors on the plasma membrane of the postsynaptic cell. These signals either depolarize the postsynaptic membrane (making the potential inside less negative), tending to induce an action potential in the cell, or hyperpolarize the postsynaptic membrane (making the potential inside more negative), inhibiting action potential induction. (b) Electron micrograph showing an axon terminus filled with synaptic vesicles forming a synapse with a postsynaptic dendrite, with its characteristic postsynaptic density. In the synaptic region, the plasma membrane of the presynaptic cell is specialized for vesicle exocytosis; synaptic vesicles containing a neurotransmitter are clustered in these regions. The opposing membrane of the postsynaptic cell (in this case, a neuron) contains receptors for the neurotransmitter. The postsynaptic density is a protein-dense specialization that contains receptors, adhesion molecules, scaffolding molecules, signaling molecules, and cytoskeletal elements.

Neurotransmitters diffuse across the synapse in about 0.5 ms and bind to receptors on the dendrite of the adjacent neuron. Binding of neurotransmitter triggers the opening or closing of specific ion channels in the plasma membrane of *postsynaptic cell* dendrites, leading to changes in the membrane potential in this localized area of the postsynaptic cell. Generally these changes depolarize the postsynaptic membrane. The local depolarization, if large enough, triggers an action potential in the axon. This type of chemical neurotransmission is unidirectional, from the axon termini of the presynaptic cell to dendrites of the postsynaptic cell.

In some synapses, the effect of the neurotransmitters is to hyperpolarize and therefore lower the likelihood of an action potential in the postsynaptic cell. A single axon in the central nervous system can synapse with many neurons and induce responses in all of them simultaneously. Conversely, sometimes multiple neurons must act on the postsynaptic cell roughly synchronously to have a strong enough impact to trigger an action potential. Neuronal integration of depolarizing and hyperpolarizing signals determines the likelihood of an action potential. Thus neurons employ a combination of extremely fast electrical transmission along the axon with rapid chemical communication between cells. This is known as *electrochemical signaling*.

The Nervous System Uses Signaling Circuits Composed of Multiple Types of Neurons

In complex multicellular animals, neurons form signaling circuits composed of multiple, distinct types of neurons. In the spinal cord, signaling circuits that relay information between peripheral and central nervous systems consist of three basic types of nerve cells: afferent neurons, interneurons, and efferent neurons. **Afferent neurons**, also known as *sensory neurons*, carry nerve impulses from receptors or sense organs toward the central nervous system (i.e., the brain and spinal cord). These neurons report an event that has

happened, like the arrival of a flash of light or the movement of a muscle. A touch or a painful stimulus creates a sensation in the brain only after information about the stimulus travels there via afferent nerve pathways. **Efferent neurons**, also known as *effector neurons*, carry nerve impulses away from the central nervous system to generate a response. A motor neuron, for example, carries a signal to a muscle to stimulate its contraction (see Figure 23-1d); other effector neurons stimulate hormone secretion by endocrine cells. Interneurons, the largest group, relay signals from afferent to efferent neurons and to other interneurons as part of a neural pathway. An interneuron can bridge multiple neurons, allowing integration or divergence of signals and sometimes extending the reach of a signal. In a simple type of circuit called a *reflex arc*, interneurons connect multiple sensory and motor neurons, allowing one sensory neuron to affect multiple motor neurons and one motor neuron to be affected by multiple sensory neurons; in this way, interneurons integrate and enhance reflexes. For example, the knee-jerk reflex in humans, illustrated in Figure 23-4, involves a complex reflex arc in which one muscle is stimulated to contract while another is inhibited from contracting. The reflex also sends information to the brain to announce what happened. Such circuits allow an organism to respond to a sensory input by the coordinated action of sets of muscles that together achieve a single purpose.

FIGURE 23-4 The knee-jerk reflex. A tap of the hammer stretches the quadriceps muscle, thus triggering electrical activity in the stretch receptor sensory neuron. The action potential, traveling in the direction of the top blue arrow, sends signals to the brain, so we are aware of what is happening, and also to two kinds of cells in the dorsal-root ganglion that is located in the spinal cord. One cell, a motor neuron that connects back to the quadriceps (red), stimulates muscle contraction so that you kick the person who hammered your knee. The second connection activates (or "excites") an inhibitory interneuron (black). The interneuron has a damping effect, blocking activity by a flexor motor neuron (green) that would in other circumstances activate the hamstring muscle that opposes the quadriceps. In this way, relaxation of the hamstring is coupled to contraction of the quadriceps. This is a reflex because movement requires no conscious decision.

The simple signaling circuits described above, however, do not directly explain higher order brain functions such as reasoning, computation, and memory development. Neurons in these circuits include an array of excitatory neurons, which promote action potential firing in a target neuron; inhibitory neurons, which inhibit action potential firing in a target neuron; and neuromodulatory neurons, which modulate the threshold for action potential firing in

a target neuron. Typical neurons in the brain receive signals from up to a thousand other neurons and, in turn, can direct chemical signals to many other neurons. The output of the nervous system depends on its circuit properties — the amount of wiring, or interconnections, between neurons and the strength of these interconnections. As complex and diverse as neural circuits are, they are comprised of a few basic patterns. These include divergence, in which one presynaptic neuron makes connections with many postsynaptic neurons; convergence, in which one postsynaptic neuron receives inputs from many presynaptic neurons; and feedback, in which the output of a postsynaptic neuron feeds back onto a presynaptic neuron or even onto itself (Figure 23-5). Feedback circuits form what are known as *closed loops*, in which the output of a system is used as the input. In a positive feedback circuit, the output sustains or increases the activity of the initial input. In a negative feedback circuit, the output inhibits the activity of the initial input.

FIGURE 23-5 Common patterns in neural circuits. Neurons connect to one another to form functional circuits. Shown are three common patterns of connectivity that are found in many neural circuits. (a) In divergent neural circuits, a single neuron sends axonal branches to contact many different target neurons. (b) In convergent neural circuits, many different neurons send axonal branches that converge to contact a single target neuron. (c) In feedback

circuits, a neuron sends an axon to communicate with a neuron that is presynaptic to it. Combinations of these and other patterns of interconnectivity function to communicate information within neural circuits.

Glial Cells Form Myelin Sheaths and Support Neurons

Neurons are not the only essential cells in the human brain. **Glial cells** (also known as *neuroglia* or simply *glia*), which play many roles in the brain but do not themselves conduct electrical impulses, are present in the brain in large numbers. While many textbooks claim that glia outnumber neurons by 10 to 1, recent experiments have suggested that the ratio of glia to neurons in the human brain is closer to 1:1, although there is significant variability between species and brain areas. As described above, of the four principal types of glia, two produce myelin sheaths — the insulation that surrounds neuronal axons (see Figure 23-1d): **oligodendrocytes** make sheaths for the central nervous system (CNS), and **Schwann cells** make them for the peripheral nervous system (PNS). (Both types of glia are discussed in more detail in Section 23.2.) Astrocytes, a third type of glia, provide growth factors and other signals to neurons and also receive signals from neurons. A fourth type of glia, *microglia*, constitutes a part of the CNS immune system. While microglia are not related by lineage to neurons or to other glia, they do play important roles in brain development and health. We describe the function of astrocytes below; oligodendrocytes and

Schwann cells will be discussed in Section 23.2, and microglia in Section 23.3.

Astrocytes, named for their starlike shape (Figure 23-6), constitute about a third of the brain's mass and ~20 percent to 40 percent of the brain's cells. Recent studies have revealed a remarkable molecular, physiological, and functional diversity of astrocytes. Understanding the function of astrocytes in brain function is an area of active investigation. Astrocytes surround many synapses and dendrites; the Ca^{2+}, K^{+}, Na^{+}, and Cl^{-} channels found in astrocyte plasma membranes influence the concentration of free ions in the extracellular space, thus affecting the membrane potentials of neurons and of the astrocytes themselves. Astrocytes produce abundant extracellular matrix proteins, some of which are used as guidance cues by migrating neurons. They also produce a host of growth factors that carry a variety of types of information to neurons. In addition, astrocytes release several factors that are necessary for proper synapse formation between neurons, as discussed in Section 23.3. Astrocytes are joined to each other by gap junctions (see Figure 20-21 for structure of gap junctions), so changes in ionic composition in a given astrocyte are communicated to adjacent astrocytes. In this way, like neurons, astrocytes can also form networks, called *astrocyte syncytia*, within the nervous system.

FIGURE 23-6 Astrocytes: morphology, gap-junction-mediated networks of astrocytes, and interaction with endothelial cells at the blood-brain barrier. (a) Astrocytes are so named for their starlike shape. In this photomicrograph, astrocytes are labeled in magenta with an antibody that recognizes glial fibrillary acidic protein (GFAP), an intermediate filament protein that reveals the major branches of the astrocytes. One astrocyte in the middle of the field was also microinjected with a soluble green fluorescent dye, which shows that, in addition to the major branches (seen as white from the merged magenta and green labels), astrocytes contain many fine branches called *branchlets*. (b) Astrocytes are connected to one another through gap junctions (see Figure 20-21), through which ions such as Ca^{2+}, K^+, and Na^+ can rapidly flow from one astrocyte to another to form networks or syncytia of astrocytes. Not shown here, astrocytes also form gap junctions with neurons and

oligodendrocytes. (c) Astrocytes contribute to the blood-brain barrier. Capillaries in the brain are formed by endothelial cells that are interconnected by tight junctions that are impermeable to most molecules. Transport between cells is blocked, so only small molecules that can diffuse across plasma membranes or substances specifically transported through cells can cross the barrier. Certain astrocytes surround the blood vessels, in contact with the endothelial cells, and send secreted protein signals to induce the endothelial cells to produce a selective barrier. The endothelial cells (purple) are ensheathed by a layer of basal lamina (brown), which contains contractile cells called *pericytes* (yellow) and are contacted on the outside by astrocyte processes (blue). See N. J. Abbott, L. Rönnbäck, and E. Hansson, 2006, *Nat. Rev. Neurosci.* **7**:41–53.

[Part (a) UC San Diego, Eric Bushong, Maryann Martone, Mark Ellisman (2002) CCDB:1053, rattus norvegicus, protoplasmic astrocyte. CIL. Dataset. https://doi:org/10.7295/W9CCDB1053.]

Some astrocytes are also critical regulators of the formation of the blood-brain barrier, which controls what types of molecules can travel out of the bloodstream into the brain and vice versa (see Figure 23-6c). Blood vessels in the brain supply oxygen and remove CO_2 and deliver glucose and amino acids, with capillaries found within a few micrometers of every cell. The blood-brain barrier is formed by tight junctions (Chapter 20) between endothelial cells in brain blood vessels. Endfeet projections from astrocytes interact closely with the brain endothelial cells and with the basal lamina (see Figures 20-23 and 20-24), which contains contractile cells called *pericytes*, to regulate blood-brain barrier integrity and function. Many scientists are interested in understanding the blood-brain barrier both because it appears to break down in certain neurological diseases and because it represents a major barrier to the development of effective neurotherapeutics.

Neural Stem Cells Form Nerve and Glial Cells in the Central Nervous System

The great interest in the formation of the nervous system and in finding better ways to prevent or treat neurodegenerative diseases through cell replacement therapies has made the characterization of neural stem cells and understanding what triggers their differentiation into mature neurons and glia an important goal. Much of what we understand about neural and glial stem cells comes from studies of embryonic brain development. The earliest stages of vertebrate neural development involve the rolling up of a tube of ectoderm, the cell layer that lines the outside of the embryo and extends the length of the embryo from head to tail (Figure 23-7a). This *neural tube* will form the brain and spinal cord. Initially, the thickness of the tube is a single layer of cells, and these cells, referred to as *neuroepithelial cells*, serve as the embryonic neural stem cells (NSCs) that will give rise to the entire central nervous system. The inside of the neural tube will expand in the forebrain to form the fluid-filled compartments called *ventricles*, and the cellular layer lining the neural tube, called the *ventricular zone (VZ)*, is where most cell division will take place.

FIGURE 23-7 Formation of the neural tube and division of neural stem cells. (a) Early in vertebrate development a part of the ectoderm rolls up and separates from the rest of the cells. This forms the epidermis (gray) and the neural tube (blue). Near the interface between the two, neural crest cells form and then migrate to contribute to skin pigmentation, nerve

formation, craniofacial skeleton, heart valves, peripheral neurons, and other structures. The notochord, a rod of mesoderm for which chordates are named, provides signals that affect cell fates in the neural tube. The interior of the neural tube will become a fluid-filled series of chambers called *ventricles*. Neural stem cells located adjacent to the ventricles, described as being in the ventricular zone (VZ), will divide to form neurons that migrate radially outward to form the layers of the nervous system. (b) Early in development, in the neuroepithelium, neuroepithelial cells (NECs, yellow) divide to generate more NECs. Some are also thought to generate early neurons also called *neuroblasts* (purple). As development progresses, NECs convert into radial glial cells (RGCs). RGCs divide symmetrically or asymmetrically to generate neurons (purple) or intermediate progenitor cells (IPCs, green), which in turn generate neurons. The RGCs elongate and send a process down to the VZ and a process up to the meninges. Newly born neurons migrate along the elongated RGC to reach their final position, such that the oldest neurons are closest to the VZ and the youngest neurons are closest to the meninges. In the cortex, this means that the youngest neurons are in the most superficial cortical layers (I and II) and the oldest born neurons are in the deeper cortical layers (V and VI). (c) Near the end of embryonic development, RGCs convert into astrocyte intermediate precursor cells (aIPCs) and oligodendrocyte intermediate precursor cells (oIPCs), which in turn generate astrocytes and oligodendrocytes, respectively. See A. Kriegstein and A. Alvarez-Buylla, 2009, *Annu. Rev. Neurosci.* **32**:149–184.

Labeling and tracing experiments have been done in mouse models to determine how cells are born and where they go after birth. The embryonic neuroepithelial cells (NECs), the neural stem and progenitor cells that line the ventricle, can divide symmetrically, producing two daughter stem or progenitor cells side by side (Figure 23-7b), thereby expanding the progenitor population. Around the same time that neuron production begins, the NECs transform into radial glial cells (RGCs), which are the primary precursor cells during embryonic neurogenesis. Through a series of symmetric and asymmetric cell divisions, radial glial cells give rise to neurons and intermediate precursor cells (see Figure 23-7b). During later stages

of brain development, RGCs also give rise to glia, including both astrocytes and oligodendrocytes (Figure 23-7c).

For many years it was believed that no new nerve cells are formed in the adult brain. Most mammalian brain cells indeed stop dividing by adulthood, but some cells in the lateral ventricle, in a region called the *adult subventricular zone (SVZ)*, and in a region of the **hippocampus** (a region of the temporal lobe involved in memory formation) called the *subgranular zone (SGZ)* continue to act as stem cells to generate new neurons (Figure 23-8a). Similar to other types of stem cells, these neural stem cells are functionally defined by their ability to self-renew and differentiate into neural lineages, including neurons, astrocytes, and oligodendrocytes (Figure 23-8b). To identify and characterize neural stem cells, cells isolated from the SVZ were cultured with growth factors such as FGF2 or EGF. Some of the cells survived and proliferated in an undifferentiated state; that is, they could self-renew. In the presence of other growth factors, these undifferentiated cells gave rise to neurons, astrocytes, or oligodendrocytes. The successful establishment of self-renewing and multipotent cells from the adult brain provides strong evidence for the presence of nerve stem-cell populations. While the function of these new neurons in the adult brain is not yet understood, studies in rodents have shown that their survival is increased by enriched environments and by exercise (Figure 23-8b, bottom panel). Such studies may eventually provide the basis for therapeutic applications in neural repair in humans.

FIGURE 23-8 Neurogenesis in the adult brain. (a) New neurons are born in two regions of the adult brain, the subgranular zone (SGZ) within the dentate gyrus (DG) in the hippocampus and the subventricular zone (SVZ). Neurons derived from neural stem cells in the SVZ migrate to the olfactory bulb (OB) via the rostral medial stream (RMS) in mice. (b) Newly born neurons in the SGZ were labeled with a retrovirus that expresses GFP. Shown are sections of the DG from control mice and from mice that were allowed to exercise on a running wheel in their cages for a week. The newly born neurons are green, and the extensive dendritic branches they have developed indicate that they have survived and have become incorporated into the hippocampus. All the other cells in the hippocampus are labeled with a red nuclear marker. The dense red labeling in the DG (the sideways V-shaped structure) are the cell bodies of the granule cells. The other red cell bodies represent glial cells and inhibitory neurons. As this image illustrates, the percentage of granule cells in the DG that are newly born is very small and is significantly increased by running.

KEY CONCEPTS OF SECTION 23.1

Neurons and Glia: Building Blocks of the Nervous System

- Neurons are highly asymmetric cells composed of multiple dendrites at one end, a cell body containing the nucleus, a long axon, and axon termini.
- Neurons carry information from one end to the other using pulses of ion flow across the plasma membrane; signals are received by the dendrites and transmitted by the axons (see Figure 23-1).

- The resting potential in unstimulated neurons is −70 mV; a stimulus causes opening of channels that leads to depolarization to +50 mV (see Figure 23-2).
- The strong pulse of voltage change, called an *action potential*, travels down the axon by the opening of channels at speeds of up to 100 meters per second.
- Neurons connect to other cells via synapses. At the axon termini of the presynaptic cell the signal is converted from electrical to chemical to stimulate the postsynaptic cell.
- Upon stimulation by an action potential, axon termini release, by exocytosis, small packets of chemicals called *neurotransmitters*. Neurotransmitters diffuse across the synapse and bind to receptors in the postsynaptic cells (see Figure 23-3).
- Neurons form circuits that usually consist of afferent (sensory) neurons, interneurons, and efferent (motor) neurons.
- Neurons connect with one another to form circuits. Three fundamental patterns of neuronal connectivity include divergent, convergent, and feedback circuits (see Figure 23-5).
- Glial cells are abundant in the nervous system and serve many purposes. Two types of glial cells, oligodendrocytes and Schwann cells, build the myelin insulation that coats many neurons. Astrocytes, another type of glial cell, wrap their processes around synapses and blood vessels and promote formation of the blood-brain barrier (see Figure 23-6). Astrocytes also secrete proteins that stimulate synapse formation and participate in the formation and function of neural circuits.
- Embryonic neural stem cells in the ventricular zone give rise to all cells in the central nervous system. These stem and progenitor cells undergo a series of symmetric and asymmetric cells to produce more progenitor cells, glia, and neurons (see Figure 23-7).
- In the adult brain, new neurons are born in the subventricular zone (SVZ) and in the subgranular zone (SGZ) in the dentate gyrus region of the hippocampus (see Figure 23-8).

23.2 Voltage-Gated Ion Channels and the Propagation of Action Potentials

Information processing in the nervous system depends on signaling in neurons, which in turn depends on the function of a set of membrane channels. In Chapter 11, we learned that an electric potential of ~70 mV (cytosolic face negative) exists across the plasma membrane of all cells, including resting nerve cells. This resting membrane potential is generated by outward movement of K^+ ions through open nongated K^+ channels in the plasma membrane and is driven by the K^+ concentration gradient (greater in the cytosol than in the extracellular medium). The high cytosolic K^+ and low cytosolic Na^+ concentrations, relative to their concentrations in the extracellular medium, are generated by the plasma membrane Na^+/K^+ pump (see Figure 11-12), which uses the energy released by hydrolysis of phosphoanhydride bonds in ATP to pump Na^+ outward and K^+ inward. The entry of Na^+ ions into the cytosol from the medium is thermodynamically favored, driven both by the Na^+ concentration gradient (greater in the extracellular medium than in the cytosol) and the inside-negative membrane potential (see Figure 11-24). However, most Na^+ channels in the plasma membrane are closed in resting cells (including neurons), so little inward movement of Na^+ ions can occur (Figure 23-9a).

FIGURE 23-9 Depolarization of the plasma membrane is due to opening of gated Na^+ channels. (a) In resting neurons, a type of nongated K^+ channel (blue) is open part of the time, but the more numerous gated Na^+ channels (green) are closed. The movement of K^+ ions outward establishes the inside-negative membrane potential characteristic of most cells. (b) Opening of gated Na^+ channels permits an influx of sufficient Na^+ ions to cause a reversal of the membrane potential. In the depolarized state, voltage-gated K^+ channels open and subsequently repolarize the membrane. Note that the flows of ions are too small to have much effect on the overall concentration of either Na^+ or K^+ in the cytosol or exterior fluid.

During an action potential, some of these Na^+ channels open, allowing inward movement of Na^+ ions, which depolarizes the

membrane. Action potentials are propagated down the axon because a change in voltage in one part of the axon triggers the opening of channels in the next section of the axon. Such **voltage-gated channels** therefore lie at the heart of neural transmission. In this section, we first introduce some of the key properties of action potentials, which move rapidly along the axon from the cell body to the axon termini. We then describe how the voltage-gated channels responsible for propagating action potentials in neurons operate. In the last part of the section, we will see how the myelin sheath, produced by glial cells, increases the speed and efficiency of electrical transmission in nerve cells.

The Magnitude of the Action Potential Is Close to E_{Na} and Is Caused by Na^+ Influx Through Open Na^+ Channels

The depolarization of the plasma membrane is driven by the opening of Na^+ channels. Figure 23-9b illustrates how the membrane potential will change if enough Na^+ channels in the plasma membrane open. The resulting influx of positively charged Na^+ ions into the cytosol will more than compensate for the efflux of K^+ ions through open resting K^+ channels. The result will be a net inward movement of cations, generating an excess of positive charges on the cytosolic face of the plasma membrane and a corresponding excess of negative charges on the extracellular face

(owing to the Cl^- ions "left behind" in the extracellular medium after influx of Na^+ ions). In other words, the plasma membrane becomes depolarized to such an extent that the inside face becomes positive with respect to the external face.

Recall from Chapter 11 that the equilibrium potential of an ion is the membrane potential at which there is no net flow of that ion from one side of the membrane to the other due to the balancing of two opposing forces, the ion concentration gradient and the membrane potential. At the peak of depolarization in an action potential, the magnitude of the membrane potential is very close to the Na^+ equilibrium potential E_{Na} given by the Nernst equation (Equation 11-2), as would be expected if opening of voltage-gated Na^+ channels is responsible for generating action potentials.

Sequential Opening and Closing of Voltage-Gated Na^+ and K^+ Channels Generate Action Potentials

The cycle of changes in membrane potential and return to the resting value that constitutes an action potential lasts 1–2 milliseconds and can occur hundreds of times a second in a typical neuron (see Figure 23-2). The rapidity of these changes in membrane potential is critical to the ability of neurons to encode the intensity of stimuli by modulating the frequency of action

potential firing, with low-intensity stimuli driving lower frequency of action potential firing, and stronger stimuli driving higher frequency of action potential firing. The cyclical changes in the membrane potential result first from the opening and closing of a number of *voltage-gated Na^+ channels* (i.e., channels opened by a change in membrane potential) in a segment of the axonal plasma membrane and then from the opening and closing of *voltage-gated K^+ channels.* The role of these channels in the generation of action potentials was elucidated in classic studies done on the giant axon of the squid, in which multiple microelectrodes can be inserted without causing damage to the integrity of the plasma membrane. However, the same basic mechanism, involving voltage-gated Na^+ and K^+ channels, is used by all neurons.

Voltage-Gated Na^+ Channels

As just discussed, voltage-gated Na^+ channels are closed in resting neurons. Depolarization of the membrane (as occurs when neurotransmitter stimulates a postsynaptic cell) causes a conformational change in these channel proteins that opens a gate on the cytosolic surface of the pore, permitting Na^+ ions to pass through the pore into the cell. The greater the initial membrane depolarization, the more voltage-gated Na^+ channels that open and the more Na^+ ions that enter.

As Na^+ ions flow inward through opened channels, the excess positive charges on the cytosolic face and negative charges on the exoplasmic face diffuse a short distance away from the initial site of depolarization. This *passive spread* of positive charges on the cytosolic face and negative charges on the external face depolarizes adjacent segments of the plasma membrane, causing opening of additional voltage-gated Na^+ channels in these segments and an increase in Na^+ influx. As more Na^+ ions enter the cell, the inside of the cell membrane becomes more depolarized, causing the opening of yet more voltage-gated Na^+ channels and even more membrane depolarization, setting into motion an explosive entry of Na^+ ions. For a fraction of a millisecond, the permeability of this small segment of the membrane to Na^+ becomes vastly greater than that for K^+, and the membrane potential approaches E_{Na}, the equilibrium potential for a membrane permeable only to Na^+ ions. At this point, however, further net inward movement of Na^+ ions ceases, since the concentration gradient of Na^+ ions (greater outside than inside) is now offset by the inside-positive membrane potential. The action potential is, at its peak, close to the value of E_{Na}.

Figure 23-10 schematically depicts the critical structural features of voltage-gated Na^+ channels and the conformational changes that cause their opening and closing. In the resting state, a segment of the protein on the cytosolic face — the *gate* — obstructs the central pore, preventing passage of ions. The channel contains four

positively charged *voltage-sensing α helices*; in the resting state these helices are attracted to the inside-negative surface of the plasma membrane. A small depolarization of the membrane triggers movement of these voltage-sensing helices toward the negative charges that are building up on the exoplasmic surface, causing a conformational change in the gate that opens the channel and allows Na^+ ion flow. After about 1 ms, further Na^+ influx is prevented by movement of the cytosol-facing *channel-inactivating segment* into the open channel, blocking any further movement of Na^+ ions. As long as the membrane remains depolarized, the channel-inactivating segment remains in the channel opening; during this **refractory period**, the channel is inactivated and cannot be reopened. A few milliseconds after the inside-negative resting potential is reestablished, the channel-inactivating segment swings away from the pore and the voltage-sensing α helices return to their resting position near the cytosolic surface of the membrane. Thus the channel returns to the closed resting state, once again able to be opened by depolarization. Note the important distinction between "closed" channels and those that are "inactive" as depicted in Figure 23-10.

FIGURE 23-10 Operational model of the voltage-gated Na^+ channel. As in the K^+ channel depicted in Figure 11-20, four transmembrane domains in the protein contribute to the central pore through which ions move. The critical components that control movement of Na^+ ions are shown here in the cutaway views depicting three of the four transmembrane domains. In the closed, resting state, the voltage-sensing α helices, which have positively charged side chains every third residue, are attracted to the negative charges on the cytosolic side of the resting membrane. This keeps the gate segment near the cytosolic face in a "closed" position that blocks the channel, preventing entry of Na^+ ions (step 1). In response to a small depolarization, the voltage-sensing helices move through the phospholipid bilayer toward the outer membrane surface, causing an immediate conformational change in the gate at the cytosolic face of the protein that opens the channel (step 2). Within a fraction of a millisecond the channel-inactivating segment moves into the open channel, preventing passage of further ions (step 3). Once the membrane is repolarized, the voltage-sensing helices return to the resting position, the channel-inactivating segment is displaced from the channel opening, and the gate closes; the protein reverts to the closed, resting state and can be opened again by depolarization (step 4). See W. A. Catterall, 2001, *Nature* **409**:988; and S. B. Long et al., 2007, *Nature* **450**:376.

Voltage-Gated K^+ Channels

The repolarization of the membrane that occurs during the refractory period is due largely to opening of voltage-gated K^+ channels. The subsequent increased efflux of K^+ from the cytosol removes the excess positive charges from the cytosolic face of the plasma membrane, thereby restoring the inside-negative resting potential. For a brief instant, the membrane actually becomes hyperpolarized; at the peak of this **hyperpolarization**, the potential approaches E_K, which is more negative than the resting potential (see Figure 23-2).

Opening of the voltage-gated K^+ channels is induced by the large depolarization resulting from the action potential. Unlike voltage-gated Na^+ channels, most types of voltage-gated K^+ channels remain open as long as the membrane is depolarized and close only when the membrane potential has returned to an inside-negative value. Because the voltage-gated K^+ channels open slightly after the initial depolarization, at the height of the action potential, they sometimes are called *delayed rectifier K^+ channels*. Eventually all the voltage-gated K^+ and Na^+ channels return to their closed resting states. The only open channels in this baseline condition are the nongated or background K^+ channels, which lack voltage-sensitive transmembrane segments, and which contribute to the resting membrane potential of −60 to −70 mV (see Figure 23-9a).

The patch-clamp tracings in Figure 23-11 reveal the essential properties of voltage-gated K^+ channels (see Figure 11-22 for a

description of patch clamping). In this experiment, small segments of a neuronal plasma membrane were held (clamped) at different voltages and the flux of electric charges through the patch due to flow of K^+ ions through open K^+ channels was measured. At the modest depolarizing voltage of −10 mV, the channels in the membrane patch open infrequently and remain open for only a few milliseconds, as shown, respectively, by the number and width of the upward steps on the tracings. Further, the ion flux through them is rather small, as measured by the electric current passing through each open channel (the height of the steps). Depolarizing the membrane further to +20 mV causes these channels to open about twice as frequently; also, more K^+ ions move through each open channel (the height of the steps is greater) because the force driving cytosolic K^+ ions outward is greater at a membrane potential of +20 mV than at −10 mV. Depolarizing the membrane further to +50 mV, the value at the peak of an action potential, causes opening of more K^+ channels and also increases the flux of K^+ ions through them. Thus by opening during the peak of the action potential, these K^+ channels permit the outward movement of K^+ ions and repolarization of the membrane potential while the voltage-gated Na^+ channels are being closed and inactivated.

EXPERIMENTAL FIGURE 23-11 Probability of channel opening and current flux through individual voltage-gated K^+ channels increases with the extent of membrane depolarization. These patch-clamp tracings were obtained from patches of neuronal plasma membrane clamped at three different potentials, +50, +20, and −10 mV. The upward deviations in the current indicate the opening of K^+ channels and movement of K^+ ions outward (cytosolic to exoplasmic face) across the membrane. Increasing the membrane depolarization (i.e., the clamping voltage) from −10 mV to +50 mV increases the probability a channel will open, the time it stays open, and the amount of electric current (numbers of ions) that passes through it. pA = picoamperes.

[Data from B. S. Pallotta, K. L. Magleby, and J. N. Barrett, 1981, *Nature* **293**:471; as modified by B. Hille, 1992, *Ion Channels of Excitable Membranes,* 2d ed., Sinauer, p. 122.]

More than 100 voltage-gated K^+ channel proteins have been identified in humans and other vertebrates. As we discuss later, all these channel proteins have a similar overall structure, but they exhibit different voltage dependencies, conductivities, channel kinetics, and other functional properties.

Given the fundamental role that voltage-gated Na^+ and K^+ channels play in determining action potential firing, it is not

surprising that mutations in these channels have been identified in inherited, monogenic human epilepsies. Epilepsies are seizure disorders that affect about 1 percent of the population and that result from excessive synchronized neuronal activity in the brain. While epilepsy can arise from a variety of causes, including abnormal brain development, brain injury, and drug and alcohol abuse, some forms of epilepsy are caused by mutations in genes that encode ion channels. These diseases are called *channelopathies*. Human genetic studies have identified specific missense mutations in the Nav1.1 voltage-gated Na^+ channel that cause generalized epilepsy with febrile seizures, while loss-of-function mutations in the same channel cause Dravet's syndrome, also known as *severe myoclonic epilepsy of infancy*. A variety of mutations in the Kv7.2 and Kv7.3 voltage-gated K^+ channels cause another form of epilepsy called *benign familial neonatal convulsions*. Mutations in other voltage-gated Na^+ and K^+ channels have been identified in other forms of epilepsy and cause neuronal hyperexcitability in a variety of ways. For example, altering Na^+ channel inactivation or blocking K^+ channel–dependent repolarization of neurons both prolong the duration of action potentials, whereas decreasing the ratio of inhibitory to excitatory inputs onto neurons can lower the threshold for triggering action potentials. ■

Action Potentials Are Propagated Unidirectionally Without Diminution

An action potential begins with changes that occur in a small patch of the axonal plasma membrane near the cell body. At the peak of the action potential, passive spread of the membrane depolarization is sufficient to depolarize a neighboring segment of membrane. This causes a few voltage-gated Na^+ channels in this region to open, thereby increasing the extent of depolarization in the region and causing an explosive opening of more Na^+ channels and generation of an action potential. This depolarization soon triggers opening of voltage-gated K^+ channels and restoration of the resting potential. The action potential thus spreads as a traveling wave away from its initial site without diminution.

As noted earlier, during the refractory period voltage-gated Na^+ channels are inactivated for several milliseconds. Such refractory channels cannot conduct ion movements and cannot open during this period even if the membrane is depolarized owing to passive spread. As illustrated in Figure 23-12, the inability of Na^+ channels to reopen during the refractory period ensures that action potentials are propagated only in one direction, from the initial axon segment where they originate to the axon termini. Because the Na^+ channels upstream of the location of the action potential are still inactivated, they cannot be reopened by the small depolarization caused by passive spread. In contrast, the Na^+ channels downstream of the action potential begin to open. The refractory period of the Na^+ channels also limits the number of action potentials that a neuron

can conduct per second. This is important, since it is the frequency of action potentials that carries the information.

FIGURE 23-12 Unidirectional conduction of an action potential is due to the transient inactivation of voltage-gated Na^+ channels. At time 0, an action potential (pink line) is at the 2 mm position on the axon; the Na^+ channels at this position are open (green shading), and Na^+ ions are flowing inward. The excess Na^+ ions diffuse in both directions along the inside of the membrane, passively spreading the depolarization in both directions (curved pink arrows). Because the Na^+ channels at the 1 mm position are still inactivated (red shading), they cannot yet be reopened by the small depolarization caused by passive spread; the Na^+ channels at the downstream 3 mm position, in contrast, begin to open. Each region of the membrane is refractory (inactive) for a few milliseconds after an action potential has passed. Thus the depolarization at the 2 mm site at time 0 triggers action potentials only downstream; at 1 ms an action potential is passing the 3 mm position, and at 2 ms an action potential is passing the 4 mm position.

The depolarization of the membrane during an action potential results from movement of just a small number of Na^+ ions into a neuron and does not significantly affect the intracellular Na^+ concentration. While the flow of Na^+ and K^+ ions alters membrane potential dramatically as it is depolarized, hyperpolarized, and repolarized during an action potential cycle, it is important to note that the exchange of these ions across the membrane is small compared to the overall numbers of Na^+ and K^+ ions in the cytosol and extracellular space.

All Voltage-Gated Ion Channels Have Similar Structures

Having explained how the action potential is dependent on regulated opening and closing of voltage-gated channels, we turn to a molecular dissection of these remarkable proteins. After describing the basic structure of these channels, we will focus on three questions:

- How do these proteins sense changes in membrane potential?
- How is this change transduced into opening of the channel?
- What causes these channels to become inactivated shortly after opening?

The initial breakthrough in understanding voltage-gated ion channels came from the analysis of fruit flies (*Drosophila melanogaster*) carrying the *shaker* mutation. These flies shake vigorously under ether anesthesia, reflecting a loss of motor control and a defect in certain motor neurons that have an abnormally prolonged action potential. Researchers suspected that the *shaker* mutation caused a defect in channel function. The cloning of the gene involved confirmed that the defective protein was a voltage-gated K^+ channel. The *shaker* mutation prevents the mutant channel from opening normally immediately upon depolarization. To establish that the wild-type *shaker* gene encoded a K^+ channel, cloned wild-type *shaker* cDNA was used as a template to produce *shaker* mRNA in a cell-free system. Expression of this mRNA in frog oocytes and patch-clamp measurements on the newly synthesized channel protein showed that its functional properties were identical with those of the voltage-gated K^+ channel in the neuronal

membrane, demonstrating conclusively that the *shaker* gene encodes this K^+-channel protein.

The Shaker K^+ channel and most other voltage-gated K^+ channels that have been identified are tetrameric proteins composed of four identical subunits arranged in the membrane around a central pore. Each subunit is constructed of six membrane-spanning α helices, designated *S1–S6*, and a P segment (Figure 23-13a). The S5 and S6 helices and the P segment are structurally and functionally homologous to those in the voltage-independent background K^+ channel discussed earlier (see Figure 11-20); the S5 and S6 helices form the lining of the K^+ selectivity filter through which the ion travels. The S1–S4 helices form a rigid complex that functions as a voltage sensor (with positively charged side chains in S4 acting as the primary sensor). The N-terminal ball extending into the cytosol from S1 is the channel-inactivating segment.

FIGURE 23-13 Schematic depictions of the secondary structures of voltage-gated K^+ and Na^+ channels. (a) Voltage-gated K^+ channels are tetramers composed of four identical subunits, each containing 600–700 amino acids, and six membrane-spanning α helices, S1–S6. The N-terminus of each subunit, located in the cytosol and labeled *N*, forms a globular domain (orange ball) essential for inactivation of the open channel. The S5 and S6 helices (green) and the P segment (blue) are homologous to those in voltage-independent background K^+ channels, but each subunit contains four additional transmembrane α helices. One of these, S4 (red), is the primary voltage-sensing α helix and is assisted in this role by forming a stable complex with helices S1–S3. See C. Miller and H. Hughes, 1992, *Curr. Biol.* **2**:573; and H. P. Larsson et al., 1996, *Neuron* **16**:387. (b) Voltage-gated Na^+ channels are monomers containing 1800–2000 amino acids organized into four transmembrane domains (I–IV) that are similar to the subunits in voltage-gated K^+ channels. The single hydrophobic channel-inactivating segment (orange ball) is located in

the cytosol between domains III and IV. Voltage-gated Ca^{2+} channels have a similar overall structure. Most voltage-gated ion channels also contain regulatory (β) subunits, which are not depicted here. See W. A. Catterall, 2001, *Nature* **409**:988.

Voltage-gated Na^+ channels are monomeric proteins organized into four homologous domains, I–IV (Figure 23-13b). Each of these domains is similar to a subunit of a voltage-gated K^+ channel. However, in contrast to voltage-gated K^+ channels, which have four channel-inactivating segments, the monomeric voltage-gated channels have a single channel-inactivating segment. Except for this minor structural difference and their varying ion permeabilities, all voltage-gated ion channels are thought to function in a similar manner and to have evolved from a monomeric ancestral channel protein that contained six transmembrane α helices. In the next section, we will focus on the structures of the voltage-gated K^+ channels and briefly discuss the more recently solved Na^+ channel structure.

Voltage-Sensing S4 α Helices Move in Response to Membrane Depolarization

Over the past 20 years, determination of the crystal structures for bacterial and Shaker potassium channels and other channels has greatly advanced our understanding of channel-protein biochemistry and function. More recently, powerful developments

in cryoelectron microscopy (see Chapter 11) have enabled the determination of the structures of many additional integral membrane proteins, including voltage-gated Na^+ and K^+ channels, in their native lipid environment.

The structures of the channels reveal remarkable arrangements of the voltage-sensing domains and suggest how parts of the protein move in order to open the channel. As already noted, the K^+-channel tetramer, like the Na^+-channel monomer, has a pore whose walls are formed by helices S5 and S6 (Figure 23-14). Outside that core structure, four arms (or "paddles"), each containing helices S1–S4, protrude into the surrounding membrane and also interact with the outer sides of the S5 and S6 helices; these are the voltage sensors, and they are in minimal contact with the pore. Sensitive electrical measurements suggested that the opening of a voltage-gated Na^+ or K^+ channel is accompanied by the movement of positive charges from the cytosolic to the exoplasmic surface of the membrane. The moving parts of the protein are the rigid complexes composed of helices S1–S4; S4 accounts for much of the positive charge and is the primary voltage sensor, with a positively charged lysine or arginine every third or fourth residue (Figure 23-14d). Arginines in S4 have been measured moving as much as 1.5 nm as the channel opens, which can be compared with the ~5 nm thickness of the membrane or the 1.2 nm diameter of the α helix itself; these significant conformational changes underlie the opening of the channel pore.

FIGURE 23-14 Molecular structure of a voltage-sensitive K^+ channel. Models of the potassium channel single subunit (a) and tetramer (b) as viewed from the side, in open and closed states. The four green (S5) and four blue (S6) α helices span the membrane, with the interior of the cell at the bottom and exterior at the top. Note how the helices are tightly

packed at the bottom in the closed conformation, so that the K^+ ion cannot pass through. [Compare the distances between S5 helices as shown by the curly brackets below (a) and (b).] The S4–S5 linker (orange), located in the cytoplasm, connects the S4 helix (not shown) to the S5 helix. For clarity, helices S1 through S4 have been omitted from the model; they would normally be attached to the end of the S4–S5 linker and protrude from the molecule. (c) Ribbon diagrams of the open and closed states of the channel as viewed from the cytoplasmic face of the membrane. In the open state, but not in the closed, potassium ions (dark purple) can pass through the pore. (d) Three-dimensional structure of the voltage-sensing "paddles" comprising helixes S1–S4, with the four voltage-sensing arginine (R) residues in S4. These paddles move from near the interior to the exterior of the membrane in response to depolarization. Since each one is attached to an S4–S5 linker, each linker and its attached S5 helix is moved, in turn moving S6 helices, which opens the pore. Note that as shown in (b), the linker between S4 and S5 is pointed upward toward the exoplasmic (exterior) surface in the open channel, pulled upward by the outward movement of the S1–S4 paddles; in contrast the S4–S5 linker is pointing downward in the closed channel when the S1–S4 paddles are nearer the cytosolic surface.

[Data from X. Chen et al., 2010, *Proc. Nat'l Acad. Sci. USA* **107**:11352, PDB ID 3lut; and Y. Zhou et al., 2001, *Nature* **414**:43–48, PDB ID based on 1k4c.]

In the resting state, the positive charges on the S1–S4 complexes (the paddles) are attracted to the negative charges on the cytosolic face of the membrane. In the depolarized membrane, these same positive charges become attracted to the negative charges on the exoplasmic (outer) surface of the membrane, causing the S1–S4 paddles to move partly across the membrane from the cytosolic to the exoplasmic surface. This movement is depicted schematically for the voltage-gated Na^+ channel in Figure 23-10 and triggers a conformational change in the protein that opens the channel.

The most unusual aspect of the voltage-sensitive channel structures is the presence of charged groups, such as arginines, in contact with lipid. The location of the voltage sensor helps to explain earlier experiments in which a non-voltage-sensitive channel was converted into a voltage-sensing channel by adding voltage-sensing domains. Such a result would seem unlikely if the voltage sensors had to be deeply embedded in the core structure.

Studies with mutant Shaker K^+ channels support the importance of the S4 helix in voltage sensing. When one or more arginine or lysine residues in the S4 helix of the Shaker K^+ channel were replaced with neutral or acidic residues, fewer positive charges than normal moved across the membrane in response to a membrane depolarization, indicating that arginine and lysine residues in the S4 helix do indeed move across the membrane and are necessary for channel function. The structure of the open form of a mammalian voltage-gated K^+ channel has been contrasted with the closed structure of another K^+ channel family member. The results suggest a model for the opening and closing of the channel in response to movements of the voltage sensors across the membrane (see Figure 23-14a, b). In the model, the voltage sensors, composed of helices S1–S4, move in response to voltage and exert a torque on a linker helix that connects S4 to S5:

- In the open-channel conformation, the position of the S4–S5 linker forces the S6 helix to form a kink near the cytosolic surface (blue in Figure 23-14a), and the pore inside, near the

cytosolic surface, is open. The pore's 1.2 nm diameter is sufficient to accommodate hydrated K^+ ions (see Figure 23-14c).

- When the cell membrane is repolarized and the voltage sensor moves toward the cytosolic membrane surface, the S4–S5 linkers (orange in Figure 23-14b) are twisted down, toward the inside of the cell. The S6 helices are consequently straightened, squeezing the bottom of the channel closed. Thus the gate is composed of the cytosol-facing ends of the S5 and S6 helices, where the pore is narrowest.

Although voltage-gated K^+ and voltage-gated Na^+ channels share similar voltage sensor and pore structures, the structure of their ion selectivity filters and the way that they conduct ions differ significantly (as also discussed in Chapter 11). The selectivity filter of the Na^+ channel is much larger than that of the K^+ channel, even though the diameter of a Na^+ ion (0.102 nm) is smaller than that of a K^+ ion (0.138 nm). The pore of K^+ channels contains conserved amino acids that form a lining of carbonyl oxygen atoms (see Figure 11-21). As K^+ ions enter the pore, these oxygen atoms replace its waters of hydration; the smaller Na^+ ions would be too small to interact with the backbone carbonyls of the K^+ channel pore. In contrast, Na^+ ions pass through the Na^+ channel pore as water-hydrated ions. The pore of the Na^+ channel is lined by conserved, negatively charged amino acids and is large enough to fit a single, water-hydrated Na^+ ion, with the positively charged Na^+ ion interacting with the negatively charged pore residues through its

inner shell of bound water molecules. The hydrated K^+ ion is too large to fit through this pore.

The topical anesthetic lidocaine, which is commonly used to reduce pain during dental procedures or during minor surgeries (e.g., to suture cuts), works by blocking the flow of Na^+ ions through the voltage-gated Na^+ channel. Lidocaine binds to amino acid residues that line the channel pore and prevents the influx of Na^+ and thus the generation of an action potential. The binding sites for lidocaine are only available in the open state of the channel, and binding of lidocaine appears to lock the channel in the open but occluded state. ■

Movement of the Channel-Inactivating Segment into the Open Pore Blocks Ion Flow

An important characteristic of most voltage-gated channels is inactivation; that is, soon after opening they close spontaneously, forming an inactive channel that will not reopen until the membrane is repolarized. In the resting state, the globular balls at the N-termini of the four subunits in a voltage-gated K^+ channel are free in the cytosol (see Figure 23-13). Several milliseconds after the channel is opened by depolarization, one ball moves through an opening between two of the subunits and binds in a hydrophobic

pocket in the pore's central cavity, blocking the flow of K^+ ions (see Figure 23-10). After a few milliseconds, the ball is displaced from the pore, and the protein reverts to the closed, resting state. The ball-and-chain domains in K^+ channels are functionally equivalent to the channel-inactivating segment in Na^+ channels. The experimental results shown in Figure 23-15 demonstrate that inactivation of K^+ channels depends on the ball domains, occurs after channel opening, and does not require the ball domains to be covalently linked to the channel protein.

EXPERIMENTAL FIGURE 23-15 Experiments with a mutant K^+ channel lacking the N-terminal globular domains support the ball-and-chain inactivation model. The wild-type Shaker K^+ channel and a mutant form lacking the amino acids composing the N-terminal ball were expressed in *Xenopus* oocytes. The activity of the channels was monitored by the patch-clamp technique. When patches were depolarized from 0 to +30 mV, the wild-type channel opened for ~5 ms and then closed (red curve). The mutant channel opened normally but could not close (green curve). When a chemically synthesized ball peptide was added to the cytosolic face of the patch, the

mutant channel opened normally and then closed (blue curve). This demonstrated that the added peptide inactivated the channel after it opened and that the ball does not have to be tethered to the protein in order to function.

[Data from W. N. Zagotta, T. Hoshi, and R. W. Aldrich, 1990, *Science* **250**:568.]

The single channel-inactivating segment in voltage-gated Na^+ channels contains a conserved hydrophobic motif composed of isoleucine, phenylalanine, methionine, and threonine (see Figure 23-13b). Like the longer ball-and-chain domain in K^+ channels, this segment folds into and blocks the Na^+-conducting pore until the membrane is repolarized.

Myelination Increases the Velocity of Impulse Conduction

As we have seen, action potentials are triggered by the passage of ions through Na^+ and K^+ channels in the axon membrane. Action potentials can move down an unmyelinated axon without diminution at speeds up to 1 meter per second. Even such fast speeds are insufficient to permit the complex movements typical of animals. In adult humans, for instance, the cell bodies of motor neurons innervating leg muscles are located in the spinal cord, and the axons are about a meter in length. The coordinated muscle contractions required for walking, running, and similar movements would be impossible if it took 1 second for an action potential to

move from the spinal cord down the axon of a motor neuron to a leg muscle. The solution is to wrap cells in insulation that increases the rate of movement of an action potential. The insulation is called a *myelin sheath* (see Figure 23-1d). The presence of a myelin sheath around an axon increases the velocity of impulse conduction to 10–100 meters per second. As a result, in a typical human motor neuron, an action potential can travel the length of a 1-meter-long axon and stimulate a muscle to contract within 0.01 seconds.

In nonmyelinated neurons, the conduction velocity of an action potential is roughly proportional to the diameter of the axon, because a thicker axon will have a greater number of ions that can diffuse. The human brain is packed with relatively small, myelinated neurons. If the neurons in the human brain were not myelinated, their axonal diameters would have to increase about 10,000-fold to achieve the same conduction velocities as myelinated neurons. Thus vertebrate brains, with their densely packed neurons, never could have evolved without myelin.

The vertebrate brain and spinal cord can be divided into gray and white matter (Figure 23-16), with the gray matter consisting of neuronal and glial cell bodies and unmyelinated processes, and the white matter consisting of myelin-ensheathed axon tracts, with the lipid-rich myelin imparting the white color. The difference in tissue density can also be detected using brain imaging techniques such as computerized tomography (CT) scanning and magnetic resonance

imaging (MRI; Figure 23-16b). These methods can be used to differentiate disease processes that affect myelin from those that affect neurons.

FIGURE 23-16 Gray and white matter in the central nervous system. The vertebrate brain and spinal cord can be divided into "gray matter," consisting of neuronal and glial cell bodies and unmyelinated processes, and "white matter" consisting of myelin-ensheathed axon tracts. The differences in density and lipid composition results in visible differences at the level of tissue histology, shown for the spinal cord and the cerebrum in (a). The differences in tissue density are also detected using imaging techniques such as magnetic resonance imaging (MRI) of the cerebrum (b).

Action Potentials "Jump" from Node to Node in Myelinated Axons

The myelin sheath surrounding an axon is formed from many glial cells. Each region of myelin formed by an individual glial cell is separated from the next region by an unmyelinated area of axonal membrane about 1 μm in length called the **node of Ranvier** (or simply, "node"; see Figure 23-1d). The axonal membrane is in direct contact with the extracellular fluid only at the nodes, and the myelin covering prevents any ion movement into or out of the axon except at the nodes. Moreover, voltage-gated Na^+ and Na^+/K^+ pumps, which maintain the ionic gradients in the axon, are present in high concentrations in the nodes, while K^+ channels are in high concentrations adjacent to the nodes.

As a consequence of this localization, the inward movement of Na^+ ions that generates the action potential can occur only at the myelin-free nodes (Figure 23-17). The excess cytosolic positive ions generated at a node during the membrane depolarization associated with Na^+ movement into the cytosol as part of an action potential spread passively through the axonal cytosol to the next node with very little loss or attenuation, since they cannot cross the myelinated axonal membrane. In this way, a depolarization at one node spreads rapidly to the next node and induces an action potential there, effectively permitting the action potential to jump from node to node, in a kind of transmission called **saltatory conduction**. This mode of transmission allows for both faster signaling and narrower axons seen in vertebrate animals.

FIGURE 23-17 Conduction of action potentials in myelinated axons. Because the myelin layer renders the axon impermeable to ion movement across its membrane and because voltage-gated Na^+ channels are found only on axonal membrane at the nodes of Ranvier, the influx of Na^+ ions associated with an action potential can occur only at nodes. When an action potential is generated at one node (step 1), the excess positive ions in the cytosol, which cannot move outward across the sheath, diffuse rapidly down the axon, causing sufficient depolarization at the next node (step 2) to induce an action potential at that node (step 3). By this mechanism the action potential jumps from node to node along the axon.

Two Types of Glia Produce Myelin Sheaths

Myelin sheaths are produced by two types of glial cells present in the nervous system: oligodendrocytes make sheaths for the central nervous system (CNS), and Schwann cells make them for the peripheral nervous system (PNS) (Figure 23-18). For reasons that are not understood, not all axons are myelinated.

FIGURE 23-18 Two types of glial cells make myelin sheaths. (a) A single oligodendrocyte in the central nervous system can myelinate segments of multiple axons. (b) Each Schwann cell insulates a section of a single peripheral nervous system axon. See B. Stevens, 2003, *Curr. Biol.* **13**:R469, and D. L. Sherman and P. J. Brophy, 2005, *Nat. Rev. Neurosci*. **6**:683–690.

Oligodendrocytes

Oligodendrocytes form the spiral myelin sheath around axons of the central nervous system (Figure 23-18a). Each oligodendrocyte provides myelin sheaths to segments of multiple neurons. The major protein constituents are myelin basic protein (MBP) and proteolipid protein (PLP). MBP, a peripheral membrane protein found in both the central and peripheral nervous systems, has seven RNA-splicing variants that encode different forms of the protein. It is synthesized by ribosomes located in the growing myelin sheath, an example of specific transport of mRNAs to a distal cell region (Chapter 10). MBP mRNA undergoes microtubule-dependent transport to distal oligodendrocyte processes, where its local translation contributes to the formation of the myelin sheath.

Damage to proteins produced by oligodendrocytes underlies a prevalent human neurological disease, multiple sclerosis (MS). MS is usually characterized by spasms and weakness in one or more limbs, bladder dysfunction, local sensory losses, and visual disturbances. This disorder, the prototype *demyelinating disease*, is caused by patchy loss of myelin in areas of the brain and spinal cord. In MS patients, conduction of action potentials by the demyelinated neurons is slowed, and the Na^+ channels spread outward from the nodes, lowering their nodal concentration. The cause of the disease is not known but is believed to involve the body's production of auto-antibodies (antibodies that bind to normal body proteins) that react with and attack myelin. A mouse mutant, *shiverer,* has a deletion of much of the *MBP* gene, leading to tremors,

convulsions, and early death. Similarly, a human mutation (Pelizaeus–Merzbacher disease) and a mouse mutation (*jimpy*) in the gene coding for the other major protein of CNS myelin, PLP, cause loss of oligodendrocytes and inadequate myelination. A number of new drugs to treat MS, many targeting the immune system, have recently been approved by the FDA, and many more MS drugs are currently in clinical trials. ■

Schwann Cells

Schwann cells form myelin sheaths around the axons of neurons in the PNS. A Schwann cell myelin sheath is a remarkable spiral wrap (Figure 23-18b). A long axon can have as many as several hundred Schwann cells along its length, each contributing myelin insulation to an *internode* stretch of about 1–1.5 μm of axon. Mutations in mice that eliminate Schwann cells cause the death of most neurons.

In contrast to oligodendrocytes, each Schwann cell myelinates only one axon. The sheaths are composed of about 70 percent lipid (rich in cholesterol) and 30 percent protein. In the PNS, the principal protein constituent (~80 percent) of myelin is called *protein 0* (P_0), an integral membrane protein that has immunoglobulin (Ig) domains. MBP is also an abundant component. The extracellular Ig domains of P_0 bind together the surfaces of sequential wraps around the axon to compact the spiral of myelin sheath (Figure 23-19). Other proteins play this kind of role in the CNS.

FIGURE 23-19 Formation and structure of a myelin sheath in the peripheral nervous system (PNS). (a) At high magnification the specialized spiral myelin membrane appears as a series of layers, or lamellae, of phospholipid bilayers wrapped around the axon. (b) Close-up cartoon of three layers of the myelin membrane spiral. The two most abundant integral myelin membrane proteins, P_0 and PMP22, are produced only by Schwann cells. The exoplasmic domains of P_0 proteins, on opposite membrane surfaces associate with one another, thereby zipping together the exoplasmic membrane surfaces in close apposition. Close apposition of the cytosolic faces of the membrane may result from binding of the cytosolic tail of each P_0 protein to phospholipids in the opposite membrane. PMP22 may also contribute to membrane compaction. Myelin basic protein (MBP), a cytosolic protein, remains between the closely apposed membranes as the cytosol is squeezed out. See L. Shapiro et al., 1996, *Neuron* **17**:435; and E. J. Arroyo and S. S. Scherer, 2000, *Histochem. Cell Biol.* **113**:1.

In humans, peripheral myelin, like CNS myelin, is a target of autoimmune disease, mainly involving the formation of antibodies against P_0. The Guillain-Barre syndrome (GBS), also known as *acute inflammatory demyelinating polyneuropathy,* is one such disease. GBS is the most common cause of rapid-onset paralysis, occurring at a frequency of one person out of 100,000. The cause is unknown, although it usually follows an acute infectious illness and is thought to involve an immune attack on the PNS. The common inherited

neurological disorder called *Charcot-Marie-Tooth disease type 1A,* which damages peripheral motor and sensory nerve function, is due to overexpression of the gene that encodes PMP22 protein, another constituent of peripheral nerve myelin. ■

Interactions between glia and neurons control the placement and spacing of myelin sheaths and the assembly of nerve-transmission machinery at the nodes of Ranvier. For example, a high concentration of voltage-gated Na^+ channels and Na^+/K^+ pumps, which is critical to the rise in membrane voltage during action potential generation, congregates at the nodes of Ranvier through interactions with cytoskeletal proteins. The activity of these cytoskeletal proteins is modulated by interactions between cell-adhesion molecules on glia and neurons. The regions adjacent to the myelin-free nodes are called *paranodes* and consist of specialized junctions between the myelin and the axonal membrane formed by interactions between cell-adhesion molecules described in the next paragraph. These junctions serve to restrict the movement of ion channels within the axonal membrane; they separate the nodes from a region called the *juxtaparanode,* which is enriched in voltage-gated K^+ channels. These K^+ channels mediate the return of the membrane voltage to baseline after an action potential, and the physical separation of the Na^+ and K^+ channels contributes to the efficient propagation of action potentials.

Light-Activated Ion Channels and Optogenetics

Unicellular flagellates such as *Chlamydomonas* (Figure 1-23b) respond rapidly to light through *phototaxis*, which guides them toward the light, or *photophobia*, which prevents them from moving toward the light. These rapid *photomotility* responses are mediated by light-activated cation channels that reside in a specialized photoreceptive organelle called the *eyespot*. The first light-activated channel to be cloned was from the green algae *Chlamydomonas reinhardtii*. This channel, called *channelrhodopsin*, consists of a seven-transmembrane protein covalently linked to a photo-isomerizable chromophore, all-*trans*-retinal (Figure 23-20a, b). This is the same chromophore that is used to detect photons in the eye, as discussed in Chapter 15 (see Figure 15-34). When all-*trans*-retinal absorbs a photon, it converts to 13-*cis*-retinal, which induces a conformational change in the channel protein, leading to the opening of a pore with a diameter of approximately 0.6 nm and the rapid influx of cations. Channelrhodopsins are nonselective cation channels that conduct H^+, Na^+, K^+, and Ca^{2+} ions. Many other light-activated cation channels have now been identified, and genetic engineering approaches have generated a series of designer channelrhodopsins that are activated or inactivated by specific wavelengths and intensities of light and selective for distinct cations. These advances have given rise to the exciting new field of **optogenetics**, in which channelrhodopsins are expressed in

electrically excitable cells, permitting the use of light to rapidly and selectively manipulate the membrane potential of the cell (Figure 23-20c).

FIGURE 23-20 Channelrhodopsins and optogenetics: activating neurons with light. (a) Light-activated ion channels. Channelrhodopsins are light-activated cation channels. The channel has seven transmembrane domains and is covalently linked to the photo-isomerizable chromophore all-*trans*-retinal. (b) All-*trans*-retinal absorbs blue light (~470 nm) and changes to the 13-*cis*-retinal conformation. This leads to a conformational change in the channel, opening a pore through which cations can flow. Opening of channelrhodopsin, shown in

(a), leads to influx of Na^+ from the extracellular solution into the cell, resulting in rapid depolarization of excitable cells. When the light is removed, retinal returns to the all-*trans* conformation and the channel closes. This is shown in (c) where illumination of a neuron expressing channelrhodopsin with blue light triggers action potentials as long as the light is on. See J. Wong, O. J. Abilez, and E. Kuhl, 2012, *J. Mech. Phys. Solids* **60**:1158–1178.

Optogenetic approaches have revolutionized the study of neuronal circuits in the brain because they allow neuroscientists to directly test the effect of neural circuit activity on behavior, rather than to simply record neural activity and correlate it with behavior. A common experimental approach is to make transgenic mice in which channelrhodopsin is expressed under the control of a cell-type-specific promoter (described in Chapter 6) so that only a subset of neurons in the brain express the protein. A window is then made in the skull, and lasers are used to illuminate channelrhodopsin-expressing cells near the surface of the brain, or alternatively a fiber-optic cable is used to deliver light to channelrhodopsin-expressing cells in deeper brain regions. The light triggers action potentials in the neurons, activating their circuits. By examining the behavior of the mouse, one can link the circuit with a specific behavior.

As one example of this type of experiment, the identity of the neurons in the brain that mediate thirst was discovered using optogenetics. To do this, channelrhodopsin was expressed in a region of the hypothalamus called the *subfornical organ (SFO)* in

mice (Figure 23-21). In one mouse line, channelrhodopsin was expressed exclusively in excitatory neurons, and in the other mouse line, it was expressed in inhibitory neurons. Light was delivered to the SFO using a fiber-optic cable; when the excitatory neurons were depolarized with light, the mice exhibited thirst (seeking water and drinking intensely), but when the inhibitory neurons were activated, thirst was suppressed. Together, these experiments demonstrate that neurons in the SFO of the hypothalamus regulate thirst, with activation of excitatory neurons promoting thirst and activation of inhibitory neurons repressing thirst. Similar approaches have been used to uncover circuits underlying many other behaviors, including locomotion, feeding and overeating, anxiety, aggression, and other social behaviors. In addition, optogenetic approaches can be used with other methods, such as calcium imaging (see Chapter 4 and Section 23.3) to map out the anatomy of specific circuits in the brain. This is done by activating a specific neuron with light and then using imaging approaches to visualize activity (e.g., by monitoring calcium dynamics) in downstream neurons.

FIGURE 23-21 Using optogenetics to dissect neural circuits mediating thirst. (a) Channelrhodopsin tagged with a fluorescent protein (YFP) was expressed in excitatory neurons in the subfornical organ (SFO) of the hypothalamus using an excitatory neuron–specific promoter. Neurons expressing channelrhodopsin-YFP were confirmed to be excitable by illumination with blue light in acute hypothalamic slices. (b) When excitatory neurons in the SFO of living mice are activated by blue light, the mice seek water and drink large volumes even if they are well hydrated.

KEY CONCEPTS OF SECTION 23.2

Voltage-Gated Ion Channels and the Propagation of Action Potentials

- Action potentials are sudden membrane depolarizations followed by rapid repolarization.
- An action potential results from the sequential and rapid opening and closing of voltage-gated Na^+ and K^+ channels (see Figure 23-9) in the plasma membrane of neurons and muscle cells.
- The excess cytosolic cations associated with an action potential generated at one point on an axon spread passively to the adjacent segment, triggering opening of voltage-gated Na^+ channels in the vicinity and thus propagation of the action potential along the axon.
- As the action potential reaches its peak, opening of voltage-gated K^+ channels permits efflux of K^+ ions, which repolarizes and then hyperpolarizes the membrane. As these channels close, the membrane returns to its resting potential, followed by a refractory period of several milliseconds (see Figures 23-2, 23-9, and 23-10).
- The action potential is propagated in only one direction, toward the axon termini, because of the absolute refractory period of the voltage-gated Na^+ channels and the brief hyperpolarization resulting from K^+ efflux (see Figure 23-12).
- Voltage-gated Na^+ channels are monomeric proteins containing four domains that are structurally and functionally similar to each of the subunits in the tetrameric voltage-gated K^+ channels. Each domain or subunit in voltage-gated cation channels contains six transmembrane α helices and a nonhelical P segment that forms the ion-selectivity pore (see Figure 23-13).
- Opening of voltage-gated channels results from movement of the positively charged S1−S4 paddles toward the extracellular side of the membrane in response to a depolarization of sufficient magnitude (see Figure 23-14).
- Closing and inactivation of voltage-gated cation channels result from movement of a cytosolic ball segment into the open pore (see Figure 23-10).
- While the voltage sensor and inactivation gate of voltage-gated K^+ channels and voltage-gated Na^+ channels are similar, the structure of the selectivity filter is different and provides specificity for the type of ion that is conducted through the channel.
- Myelination increases the rate of impulse conduction up to a hundredfold and permits the close packing of neurons characteristic of vertebrate brains.

- The central nervous system (CNS) can be divided into gray matter, composed of neuronal and glial cell bodies, and white matter, enriched in myelin-ensheathed axons (see Figure 23-16).
- In myelinated neurons, voltage-gated Na^+ channels are concentrated at the nodes of Ranvier. Depolarization at one node spreads rapidly with little attenuation to the next node, so that the action potential jumps from node to node (see Figure 23-17).
- Myelin sheaths are produced by glial cells that wrap themselves in spirals around neurons. Oligodendrocytes produce myelin for the CNS; Schwann cells, for the peripheral nervous system (PNS; see Figure 23-18).
- The field of optogenetics is revolutionizing the study of neural circuits. It involves the genetic expression of light-activated cation channels, called *channelrhodopsins*, in neurons and the use of light to specifically activate or inhibit that population of neurons (see Figure 23-20). In this way, neuroscientists can directly link specific neural circuits with specific behaviors.

23.3 Communication at Synapses

As we have discussed, electrical pulses transmit signals along neurons, but signals are transmitted between neurons and other excitable cells mainly by chemical signals. Synapses are the junctions where presynaptic neurons release these chemical signals, or neurotransmitters, which then act on postsynaptic target cells (see Figure 23-3). A target cell may be another neuron, a muscle, or a gland cell. Communication at chemical synapses usually goes in only one direction: pre- to postsynaptic cell.

Arrival of an action potential at an axon terminus in a presynaptic cell leads to opening of voltage-sensitive Ca^{2+} plasma-membrane channels and an influx of Ca^{2+}, causing a localized rise in the cytosolic Ca^{2+} concentration in the axon terminus. In turn, the rise in Ca^{2+} triggers fusion of small (40–50 nm) neurotransmitter-containing synaptic vesicles with the plasma membrane, releasing neurotransmitters into the synaptic cleft, the narrow space separating the presynaptic from the postsynaptic cell. The membrane of the postsynaptic cell is located within approximately 20 nm of the presynaptic membrane, reducing the distance the neurotransmitter must diffuse.

Neurotransmitters, small, water-soluble molecules such as glutamate (excitatory) or gamma-amino butyric acid (GABA, inhibitory), bind to receptors on the postsynaptic neuron that, in

turn, induce localized changes in the potential across its plasma membrane. If the membrane potential becomes less negative (i.e., becomes depolarized) an action potential will tend to be induced in the postsynaptic cell. Such synapses are called **excitatory synapses**, and in general involve the opening of Na^+ channels in the postsynaptic plasma membrane. In contrast, at an **inhibitory synapse**, binding of the neurotransmitter to a receptor on the postsynaptic cell causes hyperpolarization of the plasma membrane, that is, generation of a more inside-negative potential. Typically, hyperpolarization is the result of opening of Cl^- or K^+ channels in the postsynaptic plasma membrane, which tends to hinder generation of an action potential.

Neurotransmitter receptors fall into two broad classes: ligand-gated ion channels, also known as *ionotropic receptors*, which open immediately upon neurotransmitter binding, and metabotropic G protein–coupled receptors (GPCRs). Neurotransmitter binding to a GPCR induces the opening or closing of a separate ion-channel protein over a period of seconds to minutes. These so-called slow neurotransmitter receptors were discussed in Chapter 15 along with GPCRs that bind different types of ligands and modulate the activity of cytosolic proteins other than ion channels. In the central nervous system, *glutamate* and GABA bind primarily to ionotropic receptors to mediate excitation and inhibition, respectively, while neuromodulators like serotonin and dopamine usually bind to metabotropic receptors. In the peripheral nervous system, the main

neurotransmitters are acetylcholine and norepinephrine (also called *noradrenaline*), both of which are also expressed in the central nervous system.

The duration of the neurotransmitter signal depends on the amount of transmitter released by the presynaptic cell, which in turn depends on the amount of transmitter that had been stored as well as the frequency of action potentials arriving at the synapse. The duration of the signal also depends on how rapidly any unbound neurotransmitter is degraded in the synaptic cleft or transported back into the presynaptic cell. Presynaptic cell plasma membranes, as well as glia, contain transporter proteins that pump neurotransmitters across the plasma membrane back into the cell, thus keeping the extracellular concentrations of transmitter low.

In this section, we focus first on how synapses form and how they control the regulated secretion of neurotransmitters in the context of the basic principles of vesicular trafficking outlined in Chapter 14. Next we look at the mechanisms that limit the duration of the synaptic signal, and how neurotransmitter signaling is received and interpreted by the postsynaptic cell.

Formation of Synapses Requires Assembly of Presynaptic and Postsynaptic Structures

Axons extend from the cell body during development, guided by signals from other cells along the way, so that the axon termini will reach the correct location (see Section 18.8). As axons grow, they come into contact with their potential target cells, such as dendrites of other neurons, where synapses then form. In the CNS, presynaptic release sites occur frequently all along an axon and are called *en passant* ("in passing") *synapses*; in contrast, motor neurons form synapses with muscle cells only at the axon termini.

Glial cells play an essential role in synapse formation. Neurons cultured in isolation will not form synapses very efficiently, but when glia are added, the rate of synapse formation increases substantially. Astrocytes and Schwann cells send protein signals to neurons to stimulate the formation of synapses and then help to preserve them. One such signal is thrombospondin (TSP), a component of the extracellular matrix; mice lacking two *thrombospondin* genes have only 70 percent of the normal number of synapses in their brains. Mutual communication between neurons and the glia that surround them is frequent and complex, making the signals and information they carry an area of active research. New imaging approaches have revealed that astrocytes form a multitude of small branches that intercalate with neurons and ensheath synapses (see Figure 23-6a). Due to the function of astrocytes in providing glial-derived factors to promote synapse formation, many neuroscientists now propose that the synapse should be considered a tripartite structure, composed not only of

presynaptic and postsynaptic partners but also of astrocytes (see Figure 23-22).

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

FIGURE 23-22 Astrocytes and the tripartite synapse. (a) Many synapses are ensheathed by astroglial processes, as shown in this electron micrograph of a

synapse in the rodent hippocampus. The postsynaptic compartment (dendrite and dendritic spine) is highlighted in green, the presynaptic terminal in orange, and astroglial process in blue. (b) Astrocytes not only ensheath the synapse but also secrete a number of factors that promote correct synapse formation. These include thrombospondin, hevin, glypicans, and cholesterol. Indicative of the importance of astrocytes in neuronal synapse formation, when neurons are grown in cell culture, they require astrocytes for proper synapse formation and development.

At the site of a synapse, the presynaptic neuron has hundreds to thousands of synaptic vesicles, some docked at the membrane and others waiting in reserve. The release of neurotransmitter into the synaptic cleft occurs in the *active zone,* a specialized region of the plasma membrane containing a remarkable assemblage of proteins whose functions include modifying the properties of the synaptic vesicles and bringing them into position for docking and fusing with the plasma membrane. Viewed by electron microscopy, the active zone has electron-dense material and fine cytoskeletal filaments (Figure 23-23). A similarly dense region of specialized structures is seen across the synapse in the postsynaptic cell, the *postsynaptic density (PSD).* Cell-adhesion molecules that connect pre- and postsynaptic cells keep the active zone and PSD aligned. After release of synaptic vesicles in response to an action potential, the presynaptic neuron retrieves synaptic vesicle membrane proteins by **endocytosis** both within and outside the active zone.

FIGURE 23-23 Synaptic vesicles are localized in the axon terminus near the region where neurotransmitter is released. In this longitudinal section through a neuromuscular junction, the basal lamina lies in the synaptic cleft separating the neuron from the muscle membrane, which is extensively folded. Acetylcholine receptors are concentrated in the postsynaptic muscle membrane at the top and partway down the sides of the folds in the membrane.

Synapse assembly has been extensively studied at the **neuromuscular junction (NMJ)** (Figure 23-23); we will use this example in the discussion below. At NMJ synapses, **acetylcholine** is the neurotransmitter produced by motor neurons, and the acetylcholine receptor, AChR, is produced by the postsynaptic

muscle cell. Muscle cell precursors, myoblasts, when put into culture, will spontaneously fuse into multinucleate myotubes that look similar to normal muscle cells. As myotubes form, AChR is produced near the center of the cell and inserted into the myotube plasma membrane, forming diffuse membrane patches (Figure 23-24a).

FIGURE 23-24 Formation of the neuromuscular junction. (a) Motor neuron-myotube interactions initiate formation of neuromuscular junctions (NMJs). Following fusion of myoblasts to form multinucleate myotubes, the nuclei synthesize acetylcholine receptor (AChR) mRNA. The nuclei near the center of each muscle fiber synthesize significantly more AChR mRNA than other nuclei. AChRs together with MuSK receptor kinases accumulate in membrane patches near the center of the cell, the prospective synaptic region of the muscle, prior to and independent of innervation; the cell is said to be "prepatterned." The motor neuron axon termini grow toward these AChR clusters and secrete the glycoprotein Agrin. Agrin, in turn, induces clustering of the AChRs (dark red) and MuSKs around the axon termini (green), forming the NMJ. (b and c) Signaling downstream of Agrin receptors is mediated by seven proteins: Agrin, LRP4, MuSK, Dok-7, Crk, rapsyn, and acetylcholine (ACh) receptors. (b) In the absence of motor neuron innervation, LRP4, MuSK, and ACh receptors diffuse within the plasma membrane and Dok-7, Crk, and rapsyn diffuse within the cytosol of the muscle cells. (c) Upon motor neuron innervation, motor axons secrete Agrin, which stabilizes postsynaptic differentiation by binding LRP4 and activating MuSK kinase activity. Phosphorylation of tyrosines in the MuSK juxtamembrane region stimulates recruitment and tyrosine phosphorylation of Dok-7, an adapter protein that is expressed selectively in muscle, which forms a dimer, stimulates MuSK kinase activity, and recruits the adapter protein Crk. Crk is essential to activate a rapsyn-dependent pathway for clustering AChRs opposite the presynaptic axon termini. Recent work has shown that rapsyn is an E3 ligase (see Figure 3-32) that adds a ubiquitin-like modification to the ACh receptors, which is necessary for receptor clustering. The pathway for synapse-

specific transcription is less well understood but likely involves kinase-dependent activation of transcription factors that stimulate expression of multiple genes encoding proteins required for the formation of cholinergic NMJ synapses.

The formation of the neuromuscular synapse is a multistep process requiring signaling interactions between motor neurons and muscle fibers. A key player is **MuSK**, a receptor tyrosine kinase that is localized in the diffuse AChR-rich patches of the myotube plasma membrane. In ways that are not known, MuSK both induces clustering of AChRs and serves to attract the termini of growing motor neuron axons. For example, knockdown of MuSK inhibits both processes, while overexpression of MuSK in cultured muscle cells induces motor neuron growth throughout the muscle and formation of excess synapses.

Another key player is **Agrin**, a glycoprotein synthesized by developing motor neurons, transported in vesicles along axon microtubules, and secreted near the developing myotubes. Agrin binds to LRP4, a single-pass membrane-spanning protein; this stimulates an association between LRP4 and MuSK and increases MuSK kinase activity (Figure 23-24b). This leads to activation of several downstream signal transduction pathways, one of which leads to the formation of clusters of AChRs with the cytoskeletal protein rapsyn; this interaction, together with binding of other cytoskeletal proteins including actin, leads to localization of AChRs opposite the nerve termini at the neuromuscular junction. The

density of acetylcholine receptors in a mature synapse reaches is 1000-fold greater than in the plasma membrane.

While the molecular mechanisms underlying the formation of synapses in the central nervous system are less well understood, the process appears to follow a similar logic as that at NMJs, in which interactions between the pre- and postsynaptic compartments trigger a reorganization of already synthesized synaptic components. Analogous to the function of rapsyn in clustering AChRs at the neuromuscular synapse, distinct scaffolding proteins cluster neurotransmitter receptors at excitatory and inhibitory synapses in the central nervous system. A large PDZ-containing protein (see Chapter 20 for definition of PDZ domains) called *PSD95* clusters glutamate receptors at excitatory synapses, while another scaffolding protein called *gephryin* clusters GABA and glycine receptors at inhibitory synapses (Figure 23-25).

(b)

FIGURE 23-25 PSD95 and gephyrin are scaffolding proteins for excitatory and inhibitory postsynaptic compartments, respectively. (a) The PDZ-containing protein PSD95 is part of the postsynaptic density at excitatory synapses and serves as a scaffolding protein to cluster glutamate receptors at the postsynaptic membrane. The scaffolding protein gephyrin plays an analogous role at inhibitory synapses, where it clusters GABA receptors at the postsynaptic membrane. (b) PSD95 and gephyrin can be used to mark excitatory and inhibitory synapses, respectively. Shown in green are the PSD95-containing excitatory synapses and, in red, the gephyrin-containing inhibitory synapses that form on a single mouse cortical neuron in culture.

[Part (b) republished with permission from Elsevier, from G. G. Gross et al., 2013, "Recombinant Probes for Visualizing Endogenous Synaptic Proteins in Living Neurons," *Neuron* **78**(6):971–985; permission conveyed through Copyright Clearance Center, Inc.]

Pre- and postsynaptic compartments are linked by a network of trans-synaptic cell-adhesion molecules, whose adhesive interactions are so strong that it is not possible to biochemically separate the presynaptic compartment from the postsynaptic compartment. Synaptic adhesion molecules bind scaffolding proteins and cytoskeletal elements through their intracellular domains, promoting organization of protein complexes in both presynaptic and postsynaptic compartments. These adhesion molecules include cadherins, immunoglobulin-containing cell-adhesion molecules (described in Chapter 20), neurexins and neuroligins, ephrins, and Eph receptors.

Precise wiring in the nervous system involves not only synapse formation but also **synapse elimination**. At birth, most animals are born with an excess number of synapses, and neural circuit maturation involves a critical process of synaptic pruning that eliminates a large number of synapses. Synaptic pruning is dependent on neural activity, and studies indicate that the weaker synapses are eliminated while the stronger synapses are maintained. For example, at birth, each muscle cell is innervated by multiple motor neurons, but over time many of the motor neuron contacts are eliminated so that eventually each muscle cell is

innervated by a single motor neuron. This process of synapse elimination is dependent on activity in the muscle cell: if the muscle cell is pharmacologically silenced, it never loses its polyneuronal innervation.

The cell biological mechanisms underlying synapse elimination, including the mechanisms that specify which synapses should be eliminated and the process of elimination itself, are areas of active research. Many recent studies have uncovered roles for astrocytes and microglia in the phagocytosis of eliminated synapses during synaptic pruning. In addition, human genetic studies have identified specific alleles in immune genes expressed by microglia, including in components of the complement system (see Chapter 24), as major risk alleles for schizophrenia, consistent with the hypothesis that aberrant synapse elimination contributes to this psychiatric disease.

Neurotransmitters Are Transported into Synaptic Vesicles by H^+-Linked Antiport Proteins

Numerous small molecules function as neurotransmitters at various synapses. With the exception of acetylcholine, the most common neurotransmitters, as shown in Figure 23-26, are amino acids or derivatives of amino acids. Nucleotides such as ATP and the corresponding nucleosides, which lack phosphate groups, also

function as neurotransmitters. While neurons were previously thought to make only one type of neurotransmitter, more recent studies indicate that some neurons can produce and release two or more. While the types of neurotransmitters are varied and while they operate in different parts of the nervous system, their release results in one of two outcomes: either the induction of an electrical signal or its inhibition.

FIGURE 23-26 Structures of several small molecules that function as neurotransmitters. Except for acetylcholine, all of these molecules are amino acids (glycine and glutamate) or derived from the indicated amino acids. The three transmitters synthesized from tyrosine, which contain the catechol moiety (blue highlight), are referred to as *catecholamines*.

All of these neurotransmitters are synthesized in the cytosol and imported into membrane-bound synaptic vesicles within axon termini, where they are stored. These vesicles are 40–50 nm in diameter, and their lumen has a low pH, generated by operation of a V-class proton pump in the vesicle membrane. Similar to the accumulation of metabolites in plant vacuoles (see Figure 11-29), this proton concentration gradient (greater in vesicle lumen than in cytosol) drives neurotransmitter import by ligand-specific H^+-linked neurotransmitter antiporters in the vesicle membrane (see Figure 23-26).

For example, acetylcholine is synthesized in the cytosol from a precursor molecule, acetyl coenzyme A (acetyl CoA), and choline in a reaction catalyzed by choline acetyltransferase:

Synaptic vesicles take up and concentrate acetylcholine from the cytosol against a steep concentration gradient, using an H^+/acetylcholine antiporter in the vesicle membrane. As with other antiporters, the export of protons from the forming vesicle down its electrochemical gradient powers the uptake of the neurotransmitter. As an example of an evolutionary mechanism to ensure coordinate expression of these two proteins, the gene encoding this antiporter is contained entirely within the first intron of the gene encoding choline acetyltransferase.

Different H^+/neurotransmitter antiport proteins are used for import of other neurotransmitters into synaptic vesicles. For example, glutamate is imported into synaptic vesicles by a family of proteins called *vesicular glutamate transporters (VGLUTs)*. VGLUTs are highly

specific for glutamate but have rather low substrate affinity. Another family of transporters, the *vesicular GABA transporters (VGATs)* transport GABA and glycine into synaptic vesicles. Like the acetylcholine transporter, VGLUTs and VGATs are antiporters, moving glutamate and GABA or glycine into synaptic vesicles while protons move in the other direction. VGLUT and VGAT serve as useful markers for excitatory and inhibitory synaptic terminals, respectively.

Three Pools of Synaptic Vesicles Loaded with Neurotransmitter Are Present in the Presynaptic Terminal

A highly organized arrangement of cytoskeletal fibers in the axon terminus helps localize synaptic vesicles within the presynaptic terminal. The population of synaptic vesicles has been proposed to exist in three states: a small readily releasable pool, which is docked at the active zone near the plasma membrane; a larger recycling pool, which is proximal but not docked at the plasma membrane and is released with moderate stimulation; and a reserve pool, which includes the majority of synaptic vesicles in the terminal. The reserve pool is the most distal from the active zone and is released only in response to particularly strong stimuli. A family of phosphoproteins called *synapsins* tether synaptic vesicles to the actin cytoskeleton and to one another. Neuronal stimulation activates

kinases that phosphorylate synapsins to modulate synaptic vesicle tethering and thereby alter the number of synaptic vesicles available for release. Indeed, synapsin knockout mice, although viable, are prone to seizures; during repetitive stimulation of many neurons in such mice, the number of synaptic vesicles that fuse with the plasma membrane is greatly reduced.

Influx of Ca^{2+} Triggers Release of Neurotransmitters

The exocytosis of neurotransmitters from synaptic vesicles involves vesicle-targeting and fusion events similar to those that occur during the intracellular transport of secreted and plasma-membrane proteins (see Chapter 14). However, two unique features critical to synapse function differ from secretory pathways in non-neuronal cells: (1) secretion is tightly coupled to arrival of an action potential at the axon terminus, and (2) synaptic vesicles are recycled locally within the axon terminus after fusion with the plasma membrane. Figure 23-27 shows the entire cycle whereby synaptic vesicles are filled with neurotransmitter, release their contents, and are recycled.

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

FIGURE 23-27 Cycling of neurotransmitters and of synaptic vesicles in axon termini. Most synaptic vesicles are formed by endocytic recycling as depicted here (although note that some synaptic vesicles are transported from the cell body by axonal transport along microtubules). The entire cycle typically takes about 60 seconds. Step **1**: The uncoated vesicles express a V-type proton pump (orange) and a single type of H^+-neurotransmitter antiporter (blue) specific for the particular neurotransmitter, to import neurotransmitters (red dots) from the cytosol. Step **2**: Synaptic vesicles loaded with neurotransmitter move to the active zone. Step **3**: Vesicles dock at defined sites on the plasma membrane of the presynaptic cell, and the vesicle v-SNAREs called *VAMP* bind to the plasma membrane t-SNAREs, forming a SNARE complex. Synaptotagmin prevents membrane fusion and release of neurotransmitter. Botulinum toxin prevents exocytosis by proteolytically cleaving VAMP, the v-SNARE on vesicles. Step **4**: In response to a nerve impulse (action potential), voltage-gated Ca^{2+} channels in the plasma membrane open, allowing an influx of Ca^{2+} from the extracellular medium. The elevation in cytosolic Ca^{2+} leads to fusion of docked vesicles with the plasma membrane and release of neurotransmitters into the synaptic cleft (via mechanisms highlighted in Figure 23-29). Step **5**: Na^+ symporter proteins take up neurotransmitter from the synaptic cleft into the cytosol, which limits the duration of the

action potential and partially recharges the cell with transmitter. Step **6**: Vesicles are recovered by endocytosis, creating uncoated vesicles, ready to be refilled and begin the cycle anew. After clathrin/AP vesicles containing neurotransmitter transporter proteins bud inward and are pinched off in a dynamin-mediated process, they lose their coat proteins. Dynamin mutations such as *shibire* in *Drosophila* block the re-formation of synaptic vesicles, leading to paralysis. Unlike most neurotransmitters, acetylcholine is not recycled. See K. Takei et al., 1996, *J. Cell Biol.* **133**:1237; V. N. Murthy and C. F. Stevens, 1998, *Nature* **392**:497; and R. Jahn, T. Lang, and T. C. Südhof, 2003, *Cell* **112**:519.

Depolarization of the plasma membrane cannot, by itself, cause synaptic vesicles to fuse with the plasma membrane. In order to trigger vesicle fusion, an action potential must be converted into a chemical signal — namely, a localized rise in the cytosolic Ca^{2+} concentration. The transducers of the electrical signals are *voltage-gated* Ca^{2+} channels localized to the region of the plasma membrane adjacent to the synaptic vesicles. The membrane depolarization due to the arrival of an action potential opens these channels, permitting an influx of Ca^{2+} ions from the extracellular medium into the region of the axon terminus near the docked synaptic vesicles. Importantly, the rise in cytosolic Ca^{2+} is localized; it is also transient, as the excess Ca^{2+} is rapidly pumped out of the cell by plasma membrane Ca^{2+} pumps.

A single action potential leads to exocytosis of about 10 percent of synaptic vesicles in a presynaptic terminal. Membrane proteins unique to synaptic vesicles then are specifically internalized by endocytosis, usually via the same types of clathrin-coated vesicles used to recover other plasma membrane proteins by other types of

cells. After the endocytosed vesicles lose their clathrin coat, they are rapidly refilled with neurotransmitter. The ability of many neurons to fire 50 times a second is clear evidence that the recycling of vesicle membrane proteins occurs quite rapidly (see Figure 23-27). The machinery of endocytosis and exocytosis is highly conserved; it is described in more detail in Chapter 14.

The development of fluorescent Ca^{2+} indicators has provided a powerful means of visualizing synaptic activity in neurons in culture and in intact neural circuits. As discussed in Chapter 4, these indicators are fluorescent molecules that change their fluorescence emission upon Ca^{2+} binding and include both chemical indicators and genetically encoded indicators. Delivery or expression of Ca^{2+} indicators to neurons in a circuit allows experimenters to use time-lapse microscopy to monitor Ca^{2+} transients in hundreds of neurons and glia in real time. For example, expression of the genetically encoded Ca^{2+} indicator GCaMP6 in the visual cortex of mice, combined with presentation of visual stimuli and in vivo two-photon microscopy, has been used to identify the population of neurons that respond to specific orientations of visual information (Figure 23-28).

FIGURE 23-28 Calcium indicators allow visualization of activity in neural circuits. A genetically encoded calcium indicator was expressed in neurons in the mouse visual cortex. (a) A window was made in the skull of the mouse, and a microscope (indicated by the objective lens) was used to visualize calcium transients in populations of neurons in the visual cortex while the mouse was looking at gratings that moved in different directions. Individual neurons within the visual cortex respond to specific orientations of the gratings, as detected by elevations in calcium that are visualized as increases in the fluorescence of the calcium indicator. (b) Neurons were color coded according to the orientation that elicited increases in calcium (as shown below the photo). The neurons shown in yellow respond to horizontally moving gratings, and the neurons shown in cyan respond to vertically moving gratings, while the neurons shown

in green and red respond to diagonally oriented gratings. This type of experiment reveals that individual neurons are tuned to specific orientations of visual stimuli.

A Calcium-Binding Protein Regulates Fusion of Synaptic Vesicles with the Plasma Membrane

Fusion of synaptic vesicles with the plasma membrane of axon termini depends on **SNAREs**, the same types of proteins that mediate membrane fusion of other regulated secretory vesicles, and **SM proteins** (for Sec1/Munc18-like proteins). The principal v-SNARE in synaptic vesicles (VAMP) tightly binds syntaxin and SNAP-25, the principal t-SNAREs in the plasma membrane of axon termini, to form four-helix SNARE complexes. The assembly of the SNARE complex brings the synaptic vesicle membrane into close proximity to the presynaptic plasma membrane, but the formation of a fusion pore requires an additional step, association of an SM protein with syntaxin. After fusion, proteins within the axon terminus promote disassociation of VAMP from t-SNAREs, as in the fusion of secretory vesicles depicted in Figure 14-11.

Strong evidence for the role of VAMP in neurotransmitter exocytosis is provided by the mechanism of action of botulinum toxin, a bacterial protein that can cause the paralysis and death characteristic of *botulism,* a type of food poisoning. The toxin is composed of two polypeptides, one of which binds to motor neurons that release acetylcholine at synapses with muscle cells, facilitating entry of the other polypeptide, a protease, into the cytosol of the axon terminus. The only protein this protease cleaves is VAMP (see Figure 23-27, step **3**). After the botulinum protease enters an axon terminus, synaptic vesicles that are not already docked rapidly lose their ability to fuse with the plasma membrane because cleavage of VAMP prevents assembly of SNARE complexes. The resulting block in acetylcholine release at neuromuscular synapses causes paralysis. However, vesicles that are already docked exhibit remarkable resistance to the toxin, indicating that SNARE complexes may already be in a partially assembled, protease-resistant state when vesicles are docked on the presynaptic membrane.

The signal that triggers exocytosis of docked synaptic vesicles is a very localized rise in the Ca^{2+} concentration in the cytosol near vesicles from 0.1 μM, characteristic of resting cells, to 1–100 μM following arrival of an action potential in stimulated cells. The speed with which synaptic vesicles fuse with the presynaptic membrane after a rise in cytosolic Ca^{2+} (less than 1 ms) indicates that the fusion machinery is entirely assembled in the resting state and can

rapidly undergo a conformational change leading to exocytosis of neurotransmitter (Figure 23-29). A Ca^{2+}-binding protein called *synaptotagmin,* located in the membrane of synaptic vesicles, is a key component of the vesicle-fusion machinery that triggers exocytosis in response to Ca^{2+}. A protein called *complexin* is thought to bind to the α-helical bundle of an assembled v-SNARE/t-SNARE complex that bridges the synaptic vesicle and plasma membranes, preventing the final fusion step. Binding of Ca^{2+} to synaptotagmin relieves this inhibition, releasing complexin and allowing the fusion event to occur very rapidly. Mammals express multiple different synaptotagmin isoforms, each of which has a different binding affinity for Ca^{2+}, and as a result the kinetics of exocytosis depend on the particular synaptotagmin isoform expressed in the neuron.

FIGURE 23-29 Synaptotagmin- and SNARE-mediated fusion of synaptic vesicles with the plasma membrane. Only a few synaptic vesicles are docked at the presynaptic plasma membrane; these are primed for fusion with the plasma membrane. (a) The tight interconnections between the synaptic vesicle and plasma membrane are mediated in part by bundles of four α helices derived from complexes of vesicle v-SNARE (e.g., VAMP) and plasma membrane t-SNARE proteins (e.g., SNAP-25 and syntaxin; see Figure 14-11). The fusion of the two membranes is prevented by binding of complexin protein to the v-SNARE/t-SNARE complex. Synaptotagmin is composed of a short intraluminal sequence, a single transmembrane α helix that anchors it in the synaptic vesicle membrane, a linker, and two Ca^{2+}-binding domains termed *C2A* and *C2B*. Synaptotagmin without bound Ca^{2+} may also bind to the v-SNARE/t-SNARE complex and prevent membrane fusion. (b) A localized rise in Ca^{2+} allows Ca^{2+} ions to bind to synaptotagmin, altering its three-dimensional

conformation. This triggers release of the complexin fusion inhibitor, binding (or altered binding) of synaptotagmin to the v-SNARE/t-SNARE complex, instantaneous membrane fusion, and release of neurotransmitters into the extracellular space. The SM protein Munc18, which binds to syntaxin, is required for SNARE-mediated fusion, although its precise mechanisms of action are not known. See T. C. Südhof and J. E. Rothman, 2009, *Science* **323**:474; and T. C. Südhof, 2013, *Neuron* **80**:675–690.

Several lines of evidence support a role for synaptotagmin as the Ca^{2+} sensor for exocytosis of neurotransmitters. Mutant embryos of *Drosophila* and *Caenorhabditis elegans* that completely lack synaptotagmin fail to hatch and exhibit very reduced, uncoordinated muscle contractions. Larvae with partial loss-of-function mutations of synaptotagmin survive, but their neurons are defective in Ca^{2+}-stimulated vesicle exocytosis. Moreover, in mice, mutations in synaptotagmin that decrease its affinity for Ca^{2+} cause a corresponding increase in the amount of cytosolic Ca^{2+} needed to trigger rapid exocytosis.

An important characteristic of synaptic vesicle exocytosis is its speed. Synaptic vesicle fusion occurs within a few hundred microseconds after the arrival of an action potential, which is not very different from the timescale of Ca^{2+} influx through the voltage-gated Ca^{2+} channel. What makes this speed possible is the proximity of the release machinery to the voltage-gated Ca^{2+} channels. This proximity is mediated by two scaffolding proteins called *RIM* (for *R*ab3-*i*nteracting *m*olecule protein) and *RIM-BP* (for

*RIM b*inding *p*rotein), which form a complex between Rab3-containing synaptic vesicles and voltage-gated Ca^{2+} channels. In mice lacking RIM, and flies lacking RIM-BP, active zones lack voltage-gated Ca^{2+} channels, which leads to a dramatic decrease and desynchronization of neurotransmitter release.

Fly Mutants Lacking Dynamin Cannot Recycle Synaptic Vesicles

Synaptic vesicles are formed primarily by endocytic budding from the plasma membrane of axon termini (see Figure 23-27). Endocytosis usually involves clathrin-coated pits and is quite specific, in that several membrane proteins unique to the synaptic vesicles (e.g., neurotransmitter transporters) are specifically incorporated into the endocytosed vesicles and resident plasma membrane proteins (e.g., the voltage-sensitive Ca^{2+} channel) remain. In this way, synaptic-vesicle membrane proteins can be reused and the recycled vesicles refilled with neurotransmitter (see Figure 23-27, step **6**).

As in the formation of other clathrin/AP-coated vesicles, pinching off of endocytosed synaptic vesicles requires the GTP-binding protein *dynamin* (see Figure 14-20). Indeed, analysis of a temperature-sensitive *Drosophila* mutant called *shibire* (shi^{ts}), which encodes the fly dynamin protein, provided early evidence for the

role of dynamin in endocytosis. At the permissive temperature of 20 °C, the mutant flies are normal, but at the nonpermissive temperature of 30 °C, they are paralyzed (*shibire* means "paralyzed" in Japanese) because pinching off of clathrin-coated pits in neurons and other cells is blocked. When viewed in the electron microscope, the shi^{ts} neurons at 30 °C show abundant clathrin-coated pits with long necks but few clathrin-coated vesicles. Because of their inability to pinch off new synaptic vesicles, the neurons in shi^{ts} mutants eventually become depleted of synaptic vesicles when flies are shifted to the nonpermissive temperature, leading to a cessation of synaptic signaling and to paralysis.

Signaling at Synapses Is Terminated by Degradation or Reuptake of Neurotransmitters

Following neurotransmitter release from a presynaptic cell, signaling can be terminated by diffusion of a transmitter away from the synaptic cleft, but this is a slow process. Instead, one of two more rapid mechanisms terminates the action of neurotransmitters at most synapses: neurotransmitters are actively removed from the synapse by neurotransmitter transporters or destroyed by enzymes present in the synaptic cleft to prevent continued stimulation of the postsynaptic cell.

Signaling by acetylcholine is terminated when it is hydrolyzed to acetate and choline by *acetylcholinesterase,* an enzyme localized to the synaptic cleft. Choline released in this reaction is transported back into the presynaptic axon terminus by a Na^+/choline symporter and used in synthesis of more acetylcholine. The operation of this transporter is similar to that of the Na^+-linked symporters used to transport glucose into cells against a concentration gradient (see Figure 11-26).

With the exception of acetylcholine, all the neurotransmitters shown in Figure 23-26 are removed from the synaptic cleft by transport back into the axon termini that released them. These transmitters are recycled intact, as depicted in Figure 23-27 (step **5**). Transporters for GABA, norepinephrine, dopamine, and serotonin were the first to be cloned and studied. These four transport proteins are all Na^+-linked symporters. They are 60–70 percent identical in their amino acid sequences, and each is thought to contain 12 transmembrane α helices. As with other Na^+ symporters, the movement of Na^+ into the cell down its electrochemical gradient provides the energy for uptake of the neurotransmitter. To maintain electroneutrality, Cl^- often is transported via an ion channel along with the Na^+ and neurotransmitter.

Neurotransmitter transporters are targets of a variety of drugs of abuse as well as many therapeutic drugs commonly used in

psychiatry. Cocaine binds to and inhibits the transporters for norepinephrine, serotonin, and dopamine. In particular, binding of cocaine to the dopamine transporter inhibits reuptake of dopamine, causing a higher than normal concentration of dopamine to remain in the synaptic cleft and prolonging the stimulation of postsynaptic neurons. Long-lasting exposure to cocaine, as occurs with habitual use, leads to down-regulation of dopamine receptors and thus altered regulation of dopaminergic signaling. It is thought that decreased dopaminergic signaling after chronic cocaine use may contribute to depressive mood disorders and sensitize important brain reward circuits to the reinforcing effects of cocaine, leading to addiction. Similarly, therapeutic agents such as the antidepressant drugs fluoxetine (Prozac) and imipramine block serotonin reuptake, and the tricyclic antidepressant desipramine blocks norepinephrine reuptake. [Fluoxetine and similarly acting drugs such as paroxetine (Paxil) and sertraline (Zoloft) are often referred to collectively as *s*elective *s*erotonin *r*euptake *i*nhibitors (SSRIs).] These drugs also cause a higher than normal concentration of neurotransmitter to remain in the synaptic cleft and prolong the stimulation of postsynaptic neurons. ■

Exciting recent single-molecule cryoelectron microscopy studies have solved the structure of several neurotransmitter transporters, including the dopamine transporter and the serotonin transporter, in the presence and absence of drugs such as the hallucinogen ibogaine. These studies have confirmed the hypothesis that

neurotransmitter transporters share structural and functional features with the bacterial two-Na^+/one-leucine symporter (see Figures 11-25 and 11-26). This is important because past research on drugs that target neurotransmitter transporters, including antidepressants, were based on the structure of the bacterial two-Na^+/one-leucine symporter. Determination of the ultrastructure of the neurotransmitter transporters themselves not only validates these models but also provides a powerful means of developing more refined and targeted therapeutic drugs.

Opening of Acetylcholine-Gated Cation Channels Leads to Muscle Contraction

Now we look at how binding of neurotransmitters by receptors on postsynaptic cells leads to changes in the cells' membrane potential, using the communication between motor neurons and muscles as an example. At neuromuscular junctions, acetylcholine is the neurotransmitter. A single axon terminus of a frog motor neuron may contain a million or more synaptic vesicles, each containing 1000–10,000 molecules of acetylcholine; these vesicles often accumulate in rows in the active zone (see Figures 23-23 and 23-24). Such a neuron can form synapses with a single skeletal muscle cell at several hundred points.

The *nicotinic acetylcholine receptor*, which is expressed in muscle cells, is a *ligand-gated channel* that admits both K^+ and Na^+. These receptors are also produced in brain neurons and are important in learning and memory; loss of these receptors is observed in schizophrenia, epilepsy, drug addiction, and Alzheimer's disease. Antibodies against acetylcholine receptors constitute a major part of the autoimmune reactivity in the disease *myasthenia gravis*. The receptor is so named because it is bound by nicotine; it has been implicated in nicotine addiction in tobacco smokers. There are at least 14 different isoforms of the receptor, which assemble into homo- and heteropentamers with varied properties. Given their many physiological functions and their role in disease, these various isoforms are important targets for new drug development. ■

The effect of acetylcholine on this receptor can be determined by patch-clamp recording from isolated outside-out patches of muscle plasma membranes. Outside-out patch-clamp recording is a technique that measures the effects of extracellular solutes on channel receptors within the isolated patch (see Figure 11-22c). Such measurements have shown that acetylcholine causes opening of a cation channel in the receptor capable of transmitting 15,000–30,000 Na^+ and K^+ ions per millisecond. However, since the resting potential of the muscle plasma membrane is near E_K, the potassium equilibrium potential, opening of acetylcholine receptor channels causes little increase in the efflux of K^+ ions; Na^+ ions, on the other

hand, flow into the muscle cell, driven by the Na^+ electrochemical gradient.

The simultaneous increase in permeability to Na^+ and K^+ ions following binding of acetylcholine produces a net depolarization to about −15 mV from the muscle resting potential of −85 to −90 mV. As shown in Figure 23-30, this localized depolarization of the muscle plasma membrane triggers opening of voltage-gated Na^+ channels, leading to generation and conduction of an action potential in the muscle cell-surface membrane by the same mechanisms described previously for neurons. When the membrane depolarization reaches transverse tubules, specialized invaginations of the plasma membrane (see Figure 17-32b), it acts on Ca^{2+} channels in the plasma membrane apparently without causing them to open. This in turn triggers the opening of adjacent Ca^{2+}-release channels in the sarcoplasmic reticulum membrane. The subsequent flow of stored Ca^{2+} ions from the sarcoplasmic reticulum into the cytosol raises the cytosolic Ca^{2+} concentration sufficiently to induce muscle contraction.

FIGURE 23-30 Sequential activation of gated ion channels at a neuromuscular junction. Arrival of an action potential at the terminus of a presynaptic motor neuron induces (step 1) opening of voltage-gated Ca^{2+} channels in the neuron and subsequent release of acetylcholine, which (step 2) triggers opening of the ligand-gated acetylcholine receptors in the muscle plasma membrane. The open receptor channel allows an influx of Na^+ and an efflux of K^+ from the muscle cell. The Na^+ influx produces a localized depolarization of the membrane, leading to (step 3) opening of voltage-gated Na^+ channels and generation of an action potential. When the spreading depolarization reaches transverse tubules, it is sensed by voltage-gated Ca^{2+} channels in the plasma membrane. Through an unknown mechanism (indicated as a "?") these channels remain closed but influence Ca^{2+} channels in the sarcoplasmic reticulum membrane (a network of membrane-bound compartments in muscle), which release stored Ca^{2+} into the cytosol (step 4). The resulting rise in cytosolic Ca^{2+} causes muscle contraction by mechanisms discussed in Chapter 17.

Careful monitoring of the membrane potential of the muscle membrane at a synapse with a cholinergic motor neuron has demonstrated spontaneous, intermittent, and random ~2 ms depolarizations of about 0.5–1.0 mV in the absence of stimulation of the motor neuron. Each of these depolarizations is caused by the spontaneous release of acetylcholine from a single synaptic vesicle in the neuron. The release of one acetylcholine-containing synaptic vesicle results in the opening of about 3000 ion channels in the postsynaptic membrane, far short of the number needed to reach the threshold depolarization that induces an action potential. Clearly stimulation of muscle contraction by a motor neuron requires the nearly simultaneous release of acetylcholine from numerous synaptic vesicles.

All Five Subunits in the Nicotinic Acetylcholine Receptor Contribute to the Ion Channel

The excitatory nicotinic acetylcholine receptor, found at many nerve-muscle synapses, was the first ligand-gated ion channel to be purified, cloned, and characterized at the molecular level and provides a paradigm for other neurotransmitter-gated ion channels. The acetylcholine receptor from skeletal muscle is a pentameric protein with a subunit composition of $\alpha_2\beta\gamma\delta$. These four different subunit types have considerable sequence homology with each

other; on average, about 35–40 percent of the residues in any two subunits are similar, suggesting that they all derived from a common ancestral gene. The complete receptor has fivefold symmetry, and the actual cation channel is a tapered central pore lined by homologous segments from each of the five subunits (Figure 23-31). The channel opens when the receptor cooperatively binds two acetylcholine molecules to sites located at the interfaces of the αδ and αγ subunits, as shown in Figure 23-31a. Once acetylcholine is bound to a receptor, the channel is opened within a few microseconds. Studies measuring the receptor's permeability to different small cations suggest that the open ion channel is about 0.65–0.80 nm in diameter at its narrowest, in agreement with estimates from electron micrographs. This would be sufficient to allow passage of both Na^+ and K^+ ions with their shell of bound water molecules.

FIGURE 23-31 Three-dimensional structure of the nicotinic acetylcholine receptor. Three-dimensional molecular structure of the *Torpedo* nicotinic acetylcholine receptor as viewed (a) from the synaptic cleft and (b) parallel to the plane of the membrane. For clarity, only the front two subunits, α and γ, are highlighted in (b) (colors: α, red; β, green; γ, blue; δ, light blue). The two acetylcholine-binding sites are located about 3 nm from the membrane surface and are highlighted in yellow; only the one at the α-γ interface is shown in panel (b). (c) Schematic cutaway model of the pentameric receptor in the membrane. Each subunit has four membrane-spanning α helices, M1–M4; the M2 α helix (red) faces the central pore. Aspartate and glutamate side chains form two rings of negative charges, one at each end of the M2 helices, that help exclude anions from and attract cations to the channel. The gate, which is opened by binding of acetylcholine, lies within the pore.

[Data from N. Unwin, 2005, *J. Mol. Biol.* **346**:967–989, PDB ID 2bg9.]

We have described the neuromuscular junction as an excellent example of how neurotransmitters and their receptors work. Like acetylcholine, glutamate, a principal neurotransmitter used for signaling between neurons in the vertebrate brain, uses two main types of receptors. One class, termed *ionotropic glutamate receptors*, are ligand-gated ion channels that allow the flow of K^+, Na^+, and sometimes Ca^{2+} in response to glutamate binding and that work along the same principles as AChR. Glutamate also binds to a second class of receptors, coupled to G proteins. Later in this chapter, we will see how such G protein–coupled receptors (GPCRs) and ion channels function as receptors for **odorants** (molecules that activate odor receptors) and **tastants** (molecules that activate taste receptors).

Nerve Cells Integrate Many Inputs to Make an All-or-None Decision to Generate an Action Potential

At the neuromuscular junction, virtually every action potential in the presynaptic motor neuron triggers an action potential in the postsynaptic muscle cell that propagates along the muscle fiber. The situation at synapses between neurons, especially those in the brain, is much more complex because the postsynaptic neuron commonly

receives signals from many presynaptic neurons. The neurotransmitters released from presynaptic neurons may bind to an **excitatory receptor** on the postsynaptic neuron, thereby opening a channel that admits Na^+ ions or both Na^+ and K^+ ions. The acetylcholine and glutamate receptors just discussed are examples of excitatory receptors, and opening of such ion channels leads to depolarization of the postsynaptic plasma membrane, promoting generation of an action potential. In contrast, binding of a neurotransmitter to an **inhibitory receptor** (inhibiting action potential firing) on the postsynaptic cell causes opening of K^+ or Cl^- channels, leading to an efflux of additional K^+ ions or an influx of Cl^- ions. In either case, the ion flow tends to hyperpolarize the plasma membrane, which inhibits generation of an action potential in the postsynaptic cell.

A single neuron can be affected simultaneously by signals received at multiple excitatory and inhibitory synapses. The neuron continuously integrates these signals and determines whether or not to generate an action potential. In this process, the various small depolarizations and hyperpolarizations generated at synapses move along the plasma membrane from the dendrites to the cell body and then to the axon hillock, where they are integrated. An action potential is generated whenever the membrane at the axon hillock becomes depolarized to a certain voltage, which can be different for different neurons, called the *threshold potential* (Figure 23-32). Thus an action potential is generated in an all-or-nothing fashion:

depolarization to the threshold always leads to an action potential, whereas any depolarization that does not reach the threshold potential never induces it.

EXPERIMENTAL FIGURE 23-32 Incoming signals must reach the threshold potential to trigger an action potential in a postsynaptic neuron. In this example, the presynaptic neuron is generating about one action potential every 4 ms. Arrival of each action potential at the synapse causes a small change in the membrane potential at the axon hillock of the postsynaptic neuron, in this example a depolarization of ~5 mV. When multiple stimuli cause the membrane of this postsynaptic cell to become depolarized to the threshold potential, here approximately 40 mV, an action potential is induced.

Whether a neuron generates an action potential in the axon hillock depends on the balance of the timing, amplitude, and localization of all the various inputs it receives; this signal computation differs for each type of neuron. In a sense, each neuron is a tiny analog-to-digital computer that averages all the receptor activations and electrical disturbances on its membrane (analog) and makes a decision whether or not to trigger an action potential (digital) and conduct it down the axon. An action potential will always have the same magnitude in any particular neuron. As we have noted, the

frequency with which action potentials are generated in a particular neuron is the important parameter in its ability to signal other cells.

Gap Junctions Allow Direct Communication Between Neurons and Between Glia

Chemical synapses employing neurotransmitters allow one-way communication at reasonably high speed. However, sometimes signals go from cell to cell electrically, without the intervention of chemical synapses. *Electrical synapses* depend on gap-junction channels that link two cells together (see Chapter 20). The effect of gap-junction connections is to perfectly coordinate the activities of joined cells. An electrical synapse is usually *bidirectional*; either neuron can excite the other. Electrical synapses are common in the neocortex and thalamus, among others. The key feature of electrical synapses is their speed. While it takes about 0.5–5 ms for a signal to cross a chemical synapse, transmission across an electrical synapse is almost instantaneous, on the order of a fraction of a millisecond, since the cytoplasm is continuous between the cells. In addition, the presynaptic cell (the one sending the signal) does not have to reach a threshold at which it can cause an action potential in the postsynaptic cell. Instead, any electrical current continues into the next cell and causes depolarization in proportion to the current.

Gap junctions can also form between glial cells and between neurons and glia. Astrocytes in the brain are connected to one another through gap junctions, which gives rise to the generation of waves of Ca^{2+} that propagate through networks of astrocytes in the brain at a speed of 1 μm/sec. Gap junctions also form within individual Schwann cells, forming connections between the layers of myelin formed by a single Schwann cell. These gap junctions are thought to facilitate the passage of metabolites and ions between myelin layers.

An electrical synapse may contain thousands of gap-junction channels, each composed of two hemichannels, one in each apposed cell. Gap-junction channels in the neuron have a structure similar to conventional gap junctions (see Figure 20-21). Each hemichannel is an assembly of six copies of the connexin protein. Since there are about 20 mammalian connexin genes, diversity in channel structure and function can arise from the different protein components. The 1.6–2.0 nm channel itself allows the diffusion of molecules up to about 1000 Da in size and has no trouble at all accommodating ions.

KEY CONCEPTS OF SECTION 23.3

Communication at Synapses

- Synapses are the junctions between a presynaptic cell and a postsynaptic cell and are the site of communication between neurons (see Figure 23-3).

- Synapse formation is mediated by interactions between presynaptic axonal compartments and postsynaptic dendritic compartments. Cell-adhesion molecules keep the cells aligned. At the neuromuscular junction, motor neurons induce the accumulation of acetylcholine receptors in the postsynaptic muscle plasma membrane close to the forming axon terminus (see Figure 23-23).
- In presynaptic cells, low-molecular-weight neurotransmitters (e.g., acetylcholine, dopamine, epinephrine) are imported from the cytosol into synaptic vesicles by H^+-linked antiporters. V-class proton pumps maintain the low intravesicular pH that drives neurotransmitter import against a concentration gradient.
- Neurotransmitters are stored in hundreds to thousands of synaptic vesicles in the axon termini of the presynaptic cell. When an action potential arrives there, voltage-sensitive Ca^{2+} channels open and the calcium causes synaptic vesicles to fuse with the plasma membrane, releasing neurotransmitter molecules into the synapse (see Figure 23-27, step **4**).
- Neurotransmitters diffuse across the synapse and bind to receptors on the postsynaptic cell, which can be a neuron or a muscle cell. Chemical synapses of this sort are unidirectional (see Figure 23-3).
- Synaptic vesicles fuse with the plasma membrane using cellular machinery that is standard for exocytosis, including SNAREs and SM proteins. Synaptotagmin protein is the calcium sensor that detects the action potential–stimulated rise in calcium that leads to the fusion (see Figure 23-29). RIM and RIM-BP tether voltage-gated Ca^{2+} channels to the release machinery, ensuring fast coupling between action potentials and neurotransmitter release.
- Following neurotransmitter release from the presynaptic cell, vesicles are re-formed by endocytosis and recycled (see Figure 23-27, step **6**).
- Coordinated operation of four gated ion channels at the synapse of a motor neuron and a striated muscle cell leads to release of acetylcholine from the axon terminus, depolarization of the muscle membrane, generation of an action potential, and subsequent muscle contraction (see Figure 23-30).
- Neurotransmitter receptors fall into two classes: ligand-gated ion channels, which permit ion passage when open, and G protein–coupled receptors (GPCRs), which are linked to separate ion channels.
- A postsynaptic neuron generates an action potential only when the plasma membrane at the axon hillock is depolarized to the threshold potential by the summation of small depolarizations and hyperpolarizations caused by activation of multiple neuronal receptors (see Figure 23-32).
- Electrical synapses are direct gap-junction connections between neurons and between glia. Electrical synapses are extremely fast in signal transmission and are usually bidirectional.

23.4 Sensing the Environment: Touch, Pain, Taste, and Smell

Our bodies are constantly receiving signals from our environment: light, sound, smells, tastes, mechanical stimulation, heat, and cold. Our perception of these signals is mediated by the brain. In recent years dramatic progress has been made in understanding how our senses record impressions of the outside world and how the brain processes that information. For example, in Chapter 15 we described the functions of one of the two types of photoreceptors in the human retina, the *rods*, and learned how they serve as primary recipients of visual stimulation. Rods are stimulated by weak light, like moonlight, over a range of wavelengths, while the other photoreceptors, the *cones*, mediate color vision in the presence of bright light. Their photoreceptors synapse on layer upon layer of interneurons that are innervated by different combinations of photoreceptor cells. These signals are processed and interpreted by the part of the brain called the *visual cortex,* where these nerve impulses are translated into an image of the world around us.

In this section, we discuss the cellular and molecular mechanisms and specialized nerve cells underlying several of our other senses: touch, pain, taste, and smell. We see how two broad classes of receptors, ion channels and G protein–coupled receptors, function in these sensing processes. As with vision, multiple interneurons connect these sensory cells with the brain, where relayed signals are

converted into perceptions of the environment. New technologies, such as optogenetics, have been especially powerful tools in mapping these circuits. In the case of smell, each sensory neuron expresses a single odorant receptor, and we shall see how multiple sensory neurons that express the same receptor activate the same brain center. The connections between odorant binding and perception by the brain are thus direct and fairly well understood.

Mechanoreceptors Are Gated Cation Channels

Our skin, especially the skin of our fingers, is highly specialized for collecting sensory information. Our whole body, in fact, has numerous **mechanosensors** embedded in its various tissues. These sensors frequently make us aware of touch, the positions and movements of our limbs or head (proprioception), pain, and temperature, though we often go through periods when we ignore these inputs. Mammals use different sets of receptor cells to report on touch, temperature, and pain. These mechanosensory receptors are located at the terminals of a class of bipolar sensory neurons called *dorsal root ganglion cells*. The cell bodies of dorsal root ganglion cells are located in the dorsal root ganglion, adjacent to the spinal cord (see Figure 23-4), and the neurons extend an axon that bifurcates into a peripheral branch that innervates the skin and contains the mechanosensory receptors, and a central branch that

projects to the spinal cord or brain stem to relay sensory signals for processing.

Many mechanosensory receptors are Na^+ or Na^+/Ca^{2+} channels that are gated, or opened, in response to specific stimuli; activation of such receptors causes an influx of Na^+ or both Na^+ and Ca^{2+} ions, leading to membrane depolarization. Examples include the stretch and touch receptors that are activated by stretching of the cell membrane; these have been identified in a wide array of cells, ranging from vertebrate muscle and epithelial cells to yeast, plants, and even bacteria.

The cloning of genes encoding touch receptors began with the isolation of mutant strains of *C. elegans* that were insensitive to gentle body touching. Four of the genes in which mutations were isolated, *MEC-2, MEC-4, MEC-6*, and *MEC-10*, encode two subunits (MEC-4 and MEC-10) and two accessory proteins (MEC-2 and MEC-6) of a Na^+ channel in the touch-receptor cells. Studies on worms with mutations in these genes showed that these channels are necessary for transduction of a gentle body touch; biophysical studies indicated that these channels likely open directly in response to mechanical stimulation (Figure 23-33). The touch-sensitive complexes contain several other proteins essential for touch sensitivity, including subunits of novel 15-protofilament microtubules in the cytosol and specific proteins in the extracellular matrix. Similar kinds of channels are found in bacteria and lower

eukaryotes; by opening in response to membrane stretching, these channels may play a role in osmoregulation and the control of a constant cell volume.

FIGURE 23-33 The MEC-4 touch-receptor complex in *C. elegans* consists of a Na^+ channel and extracellular matrix proteins. The MEC-4 and MEC-10 proteins are the pore-forming subunits of the Na^+ channel; MEC-2 and MEC-6 are accessory subunits that enable channel activity. Mechanotransduction also requires a specialized extracellular matrix, consisting of MEC-5, a collagen isoform, and MEC-1 and MEC-9, both proteins with multiple EGF repeats. MEC-7 and MEC-12 are tubulin monomers that form novel 15-protofilament microtubules that are also required for touch sensitivity. See E. A. Lumpkin, K. L. Marshall, and A. M. Nelson, 2010, *J. Cell Biol.* **191**:237.

Two novel channels were discovered in 2010 that directly convert mechanical stimuli into cation conductance in mammalian cells, called *Piezo1* and *Piezo2* (from the Greek word *piesi*, which means "pressure"). Both form large cation-selective channels composed of three identical subunits, with each subunit containing 38

membrane-spanning domains, creating a channel that has 114 transmembrane segments! Expression of Piezo1 or Piezo2 induces mechanosensitive-cation currents in these cells. This can be assayed by expressing the channels in cell culture, and using calcium imaging to monitor the response of the cells to stretch induced by poking the cells with a small glass pipette (Figure 23-34). Reduction of Piezo2 expression in dorsal root ganglion sensory neurons in mice reduced their mechanosensitivity, and knockout of the single Piezo homolog in *Drosophila* resulted in flies with severely reduced behavioral responses to noxious mechanical stimuli. Together, these experiments show that Piezo channels mediate mechanical signal transduction.

FIGURE 23-34 Piezo channels are mechanotransducers. (a) To identify channels that transduced mechanical information, cDNAs encoding transmembrane proteins were expressed in heterologous cells, and the response to mechanical perturbation with a glass pipette was determined by patch-clamp recording (shown) or by calcium imaging (not shown). (b) When Piezo1 or Piezo2 cDNAs are expressed in cultured cells, poking the cell with a glass pipette elicits a strong inward current. (c) Piezo1 and 2 form homotrimeric cation channels. Each subunit is extremely large, with over 2000 amino acid residues and 38 transmembrane domains. The assembled channel thus contains 114 membrane spanning

domains and has a mass of over 1.2 million daltons (about the same mass as the small subunit of the ribosome)!

Pain Receptors Are Also Gated Cation Channels

Animals as diverse as snails and humans sense noxious events (the process termed *nociception*); pain receptors, called **nociceptors**, respond to mechanical change, heat, and certain toxic chemicals. Pain serves to alert us to events such as tissue damage that are capable of producing injury and evokes behaviors that promote tissue healing. Persistent pain in response to tissue injury is common, and many individuals suffer from chronic pain. Thus understanding both acute and chronic pain is a major research goal, as is the development of new types of drugs to treat pain.

One of the first mammalian pain receptors to be cloned and identified was TRPV1, a Na^+/Ca^{2+} channel that is found in many sensory pain neurons of the peripheral nervous system and is activated by a wide variety of exogenous and endogenous physical and chemical stimuli. The best known activators of TRPV1 are heat greater than 43 °C, acidic pH, and capsaicin, the molecule that makes chili peppers hot. Activation of TRPV1 receptors leads to painful, burning sensations. Numerous TRPV1 antagonists have been developed by pharmaceutical companies as possible pain

medications. However, a major side effect that has limited the utility of these drugs is that they result in an elevation in body temperature; this suggests that one function of TRPV1 is to sense and regulate body temperature and that the drugs inhibit this function. ■

In a landmark study, scientists used single-particle cryoelectron microscopy (cryoEM, see Chapter 3 and 11) to obtain a high-resolution (0.34 nm) model of the rat TRPV1 channel in the closed configuration and in two open configurations, one bound to capsaicin and the other bound to two potent TRPV1 activators, one from plant and the other from spider venom. As shown in Figure 23-35, these studies revealed that the TRPV1 channel structure is similar to that of voltage-gated ion channels (see Figure 23-13), composed of four symmetrical subunits with six transmembrane helices (S1–S6) each. However, the charged amino acids in S1–S4 that function as voltage sensors in voltage-gated ion channels are replaced by aromatic residues in TRPV1. This stabilizes the channel core so that instead of moving like voltage sensors upon depolarization, the TRPV S1–S4 helices provide an anchor for movements within the pore that are triggered by ligand binding. Two constrictions, or gates, were identified in the pore region. The spider toxin bound to the extracellular surface of the channel, near the pore helix, and locked open the extracellular end of the channel. Capsaicin and the plant toxin bound to a site deep within the membrane toward the cytoplasmic end of the pore, with binding increasing the diameter of the pore. These findings indicate that the

TRPV channel undergoes dual gating and is able to respond to diverse ligands.

FIGURE 23-35 Single-particle cyroelectron microscopy high-resolution structure of the TRPV1 channel demonstrates how this channel is activated by various chemical stimuli. The high-resolution structure of the rat TRPV1 channel was obtained by single-particle cryoelectron microscopy at 0.34 nm resolution. (a) Photomicrographs of the two-dimensional structure of the tetrameric TRPV1 channel embedded in a thin layer of vitreous ice, with a face view of the channel in the top panel, and a side view in the bottom panel. (b, *top*) Ribbon diagram of a bottom view of the channel that focuses on the S1−S4 transmembrane domains, and the pore domain formed by S5 and S6, together with linking pore (P) loops. The S1−S4 domain is similar in structure to the voltage-sensing domains in the voltage-gated K^+ and Na^+ channels (see Figure 23-14) but differ in that they do not move. (b, *bottom*) Ribbon diagram of the side view of the channel in the closed conformation, focusing on the pore domain that is formed by S5-P-S6. (c) The open

conformation was stabilized by incubating the channel with two agonists, a spider toxin (in magenta) and a plant toxin (in red). Cryoelectron density maps reveal that the spider toxin (magenta) binds to external domains of the channel, linking two subunits of the channel together via its two globular cysteine-knot domains, while the plant toxin (red) binds to a region deep within the pore. Capsaicin binds to the same sites as the plant toxin (not shown). Binding of agonists to two distinct sites indicates that the TRPV1 channel is dually gated, allowing for significant modulation of channel function.

Five Primary Tastes Are Sensed by Subsets of Cells in Each Taste Bud

We taste many chemicals, all of which are hydrophilic and nonvolatile molecules dissolved in saliva. Like the other senses, that of taste likely evolved to increase an animal's chance of survival. Many toxic substances taste bitter or acidic, and nourishing foods are broken down into molecules that taste sweet (e.g., sugars), salty, or umami (e.g., the meaty or savory taste of monosodium glutamate and other amino acids). Animals (including humans) can never be certain exactly what enters their mouth; the sense of taste enables an animal to make a quick decision — eat it, or get rid of it. Taste is less demanding of the nervous system than olfaction, because fewer types of molecules are monitored. What is impressive is the

sensitivity of taste; bitter molecules can be detected at concentrations as low as 10^{-12} M.

All tastes are sensed on all areas of the tongue, and selective cells respond preferentially to certain tastes. There are receptors for salty, sweet, sour, umami, and bitter tastes in all parts of the tongue. The receptors are of two different types: channel proteins for salty and sour tastes and seven-transmembrane-domain proteins (G protein–coupled receptors) for sweetness, umami, and bitterness. Specific membrane receptors that detect fatty acids are present on taste bud cells, and fatty taste is considered by some to be a sixth basic taste quality.

Taste buds are located in bumps in the tongue called *papillae*; each bud has a pore through which fluid carries solutes inside. Each taste bud has about 50–100 taste cells (Figure 23-36a, b), which are epithelial cells but with some of the functions of neurons. Microvilli on the taste cells' apical tips bear the **taste receptors**, directly contacting the external environment in the oral cavity and thus experiencing wide fluctuations in food-derived molecules as well as the presence of potentially harmful compounds. Cells in the tongue and other parts of the mouth are subjected to a lot of wear and tear, and taste bud cells are continuously replaced by cell divisions in the underlying epithelium.

FIGURE 23-36 The sense of taste is mediated by chemical signals. (a) The taste cells (pink) in a mammalian taste bud contact the nerve cells (yellow). The chemical signals arrive at the microvilli seen at the top. (b) Micrograph of a mammalian taste bud, showing the receptor cells. The microvilli are barely visible at the top of the taste bud, indicated by the label. (c) Sweet, bitter, and umami ligands bind specific taste GPCRs expressed in type II receptor cells, activating a phosphoinositide pathway that elevates cytosolic Ca^{2+}. Ca^{2+} in turn binds to and opens a Ca^{2+}-gated Na^+ channel, TrpM5, leading to an influx of Na^+ and membrane depolarization. The combined action of elevated Ca^{2+} and membrane depolarization opens the large pores of a membrane channel termed *Panx1*, resulting in release of ATP and probably other signaling molecules into the extracellular space. ATP and these other molecules stimulate the nerve cells that will ultimately carry the information to the brain. (d) Salt is detected by direct permeation of Na^+ ions through membrane ion channels, including the ENaC channel, directly depolarizing the plasma membrane. (e) Organic acids like acetic acid diffuse in their protonated form (H·Ac) through the plasma membrane and dissociate into an anion and proton, acidifying the cytosol. Entry of strong acids like HCl is facilitated by a proton channel in the apical membrane of the sour-sensing cells that enables protons to reach the cytosol. Intracellular H^+ is believed to block a proton-sensitive K^+ channel (as yet unidentified) and thus depolarize the membrane. Voltage-gated Ca^{2+} channels would open, leading to an elevation in cytosolic Ca^{2+} that

triggers exocytosis of synaptic vesicles that are not depicted. See N. Chaudhari and S. D. Roper, 2010, *J. Cell Biol.* **190**:285; and S. Frings, 2010, *Proc. Nat'l Acad. Sci. USA* **107**:21955.

Reception of a taste signal causes cell depolarization that triggers action potentials; these in turn cause Ca^{2+} uptake through voltage-dependent Ca^{2+} channels and release of neurotransmitters (Figure 23-36 c–e). Taste cells do not grow axons; instead, they signal over short distances to adjacent neurons. These neurons convey the information about taste through multiple connections to a region of the cortex that is specialized for taste, called the *insula*. To determine how the insula knows that a salty taste receptor as opposed to a sweet taste receptor has been activated, scientists performed two-photon imaging (see Chapter 4) of insula in mice after presentation of a specific tastant. They used calcium indicators to detect the neurons that were activated and in this way were able to monitor the activation of large numbers of neurons as calcium-dependent increases in fluorescence. These experiments revealed that four of the tastes — sweet, bitter, umami, and salty — are represented in separate, nonoverlapping regions within the insula, thereby demonstrating the existence of a gustotopic map in the brain that mediates our representation of taste.

Bitter Taste

Bitter tastants are diverse and are detected by a family of about 25–30 different G protein–coupled receptors (GPCRs) known as

T2Rs. As depicted in Figure 23-36c, all of these GPCRs activate a particular Gα isoform, called *gustducin*, which is expressed only in taste cells. However, it is the released ubiquitous Gβγ subunit of the heterotrimeric G protein that binds to and activates a specific isoform of phospholipase Cβ, which in turn generates IP_3. IP_3 triggers Ca^{2+} release from the endoplasmic reticulum (see Figure 15-28). Ca^{2+} in turn binds to and opens a Ca^{2+}-gated Na^+ channel, TRPM5, a member of the TRP family of ion channels, leading to an influx of Na^+ and membrane depolarization. The combined action of elevated Ca^{2+} and membrane depolarization opens the large pores of a membrane channel termed *Panx1*, resulting in release of ATP and probably other signaling molecules into the extracellular space. ATP is then thought to act as a neurotransmitter to stimulate the nerve cells that will ultimately carry the taste information to the brain.

Different bitter taste molecules are quite distinct in structure, which probably accounts for the need for the diverse family of T2Rs. Some T2Rs bind only 2–4 bitter-tasting compounds, whereas others bind a wider variety of bitter compounds. The first member of the T2R family to be identified came from human genetics studies that showed an important bitterness-detection gene, the *TAS2R38* gene, on chromosome 5. Mice that have five amino acid changes in the T2R protein T2R5 are unable to detect the bitter taste of cycloheximide (a protein synthesis inhibitor). Multiple T2R types are

often expressed in the same taste cell, and about 15 percent of all taste cells express T2Rs.

A clever gene regulation swap experiment was done to demonstrate the role of T2R proteins. Mice were engineered to express a bitter-taste receptor, a T2R protein, in cells that normally detect sweet tastants that attract mice. The mice developed a strong attraction for bitter tastes, evidently because the cells continued to send a "go and eat this" signal even though they were detecting bitter tastants. This experiment demonstrates that the specificity of taste cells is determined within the cells themselves and that the signals they send are interpreted according to the neural connections made by that class of cells. It implies that the T2R-expressing sweet taste receptors were wired to the region of the insula that receives bitter signals and that it was thus represented as a sweet taste.

Sweet and Umami Tastes

Sweet and umami tastants are detected by a GPCR family called the *T1Rs*, which are related to the T2Rs and that also transduce signals through a phosphoinositide signaling pathway. The three mammalian T1Rs differ from one another in a small number of amino acids. The T1Rs have very large extracellular domains that comprise the taste-binding domain of the protein. In the taste-sensing glutamate receptor, the extracellular domain closes around glutamate in a way that is described as analogous to a Venus flytrap

(see Chapter 15). Unlike most GPCRs, which generally function as monomers, T1Rs form homodimers and heterodimers, which is thought to increase the repertoire of molecules that can act as signals. However, the code of responses to different molecules is still under investigation. Mice lacking T1R2 or T1R3 fail to detect sugar; it is thought that the actual receptor is a heterodimer of the two. T1R3 appears to be a receptor for both sweet tastes and umami and that is because it detects sweets when combined with T1R2 and umami when combined with T1R1. Accordingly, taste cells express T1R1 or T1R2 but not both, as otherwise they would send an ambiguous message to the brain.

Interestingly, sweet-taste receptors are also found on the surface of certain endocrine cells in the gut; these cells also express gustducin and several other taste transduction proteins. The presence of glucose in the gut causes these cells to secrete the hormone *g*lucagon-*l*ike *p*eptide-1 (GLP-1), which in turn regulates appetite, and enhances insulin secretion and gut motility. Thus certain cells of the gut "taste" glucose through the same mechanisms used by taste cells of the tongue.

Salty Taste

The taste of salt is elicited by a wide range of Na^+ concentrations, from 10 mM to 500 mM. Salt is sensed by a member of a family of Na^+ channels called *ENaC channels* (Figure 23-36d). Indeed,

knocking out a critical ENaC subunit in taste buds impaired salty-taste detection in mice. The influx of Na^+ through the channel depolarizes the taste cell, leading to neurotransmitter release. The role of ENaC channels as salt sensors is evolutionarily ancient; ENaC proteins also detect salt when expressed in insects. In *Drosophila*, taste sensors are located in multiple places including the legs, so when the fly steps on something tasty, the proboscis extends to explore it further.

Sour Taste

Perception of sourness is due to the detection of H^+ ions. One of the sour taste receptors was recently identified as the otopetrin-1 proton channel, a member of a family of proteins originally discovered for their importance in the vestibular system. Acids are detected by the otopetrin-1 proton channel in the apical membrane of the sour-sensing cells, triggering an increase in the intracellular H^+ concentration. Protons are believed to block a proton-sensitive K^+ channel in mammals and thus depolarize the membrane (Figure 23-36e). In both salt and sour taste detection, voltage-gated Ca^{2+} channels would then open, elevate cytosolic Ca^{2+} and thus trigger exocytosis of neurotransmitter-filled synaptic vesicles.

The Largest Group of G Protein–Coupled Receptors Detect Odors

The perception of volatile airborne chemicals imposes different demands than the perception of light, sound, touch, or taste. Light is sensed by only four rhodopsin molecules, tuned to different wavelengths. Sound is detected by mechanical effects through hairs that are tuned to different wavelengths. Touch and pain requires a small number of different gated ion channels. The sense of taste measures a small number of substances dissolved in water. In contrast to all these other senses, olfactory systems can discriminate between many hundreds of volatile molecules moving through air. Discrimination between a large number of chemicals is useful in finding food or a mate, sensing pheromones, and avoiding predators, toxins, and fires. **Olfactory receptors** work with enormous sensitivity. Male moths, for example, can detect single molecules of the signals sent drifting through the air by females. In order to cope with so many signals, the olfactory system employs a large family of olfactory receptor proteins. Humans have about 700 olfactory receptor genes, of which about half are functional (the rest are unproductive pseudogenes), a remarkably large fraction of the estimated 20,000 human genes. Mice are more efficient, with more than 1200 olfactory receptor genes, of which about 800 are functional. That means 3 percent of the mouse genome is composed of olfactory receptor genes. *Drosophila* has about 60 olfactory receptor genes. Odor molecules are called *odorants*. They have diverse chemical structures, so olfactory receptors face some of the same challenges faced by antibodies and hormone receptors, specifically, the need to bind and distinguish many variants of

relatively small molecules. In this section, we will examine how olfactory receptor genes are employed, and how the brain can recognize which odor has been sensed, which are the initial stages of interpretation of our chemical world.

Olfactory receptors are seven-transmembrane-domain proteins (Figure 23-37). In mammals, olfactory receptors are produced by cells of the nasal epithelium. These cells, called *olfactory receptor neurons (ORNs),* transduce the chemical signal into action potentials. Each ORN extends a single dendrite to the luminal surface of the epithelium, from which immotile cilia extend to bind inhaled odorants from the air (Figure 23-38a). These olfactory sensory cilia are enriched in the odorant receptors and signal transduction proteins that mediate the initial transduction events. In *Drosophila,* ORNs have similar structures and are located in the antennae (Figure 23-38b).

FIGURE 23-37 Signal transduction from the olfactory GPCRs. Binding of an odorant to its cognate odorant receptor (OR) triggers activation of the trimeric G protein $G_{\alpha olf}{\cdot}G_{\beta\gamma}$, releasing the active $G_{\alpha olf}{\cdot}GTP$. Activated $G_{\alpha olf}{\cdot}GTP$ in turn activates type III adenylyl cyclase (AC3), leading to the production of cyclic AMP (cAMP) from ATP. Molecules of cAMP bind to and open the cyclic nucleotide–gated (CNG) ion channel, leading to the influx of Na^+ and Ca^{2+} and depolarizing the cell. cAMP also activates protein kinase A (PKA), which phosphorylates and thus regulates transcription factors and other intracellular proteins.

FIGURE 23-38 The structure of olfactory receptor neurons is evolutionarily conserved. (a) Vertebrate olfactory receptor neurons have one dendrite, which ends in a dendritic knob; from each dendritic knob, approximately 15 cilia extend into the nasal mucus. (b) Insect olfactory receptor neurons are morphologically similar: the bipolar neuron gives rise to a single basal axon that projects to an olfactory glomerulus in the antennal lobe. At its apical side it has a single dendritic process, from which sensory cilia extend.

[Data from U. B. Kaupp, 2010, *Nat. Rev. Neurosci*. **11**:188–200.]

In both mammals and *Drosophila*, the ORNs project their axons to the next higher level of the nervous system, which in mammals is located in the olfactory bulb of the brain. The ORN axons synapse with dendrites from *mitral neurons* in mammals (called *projection neurons* in insects); these synapses occur in the clusters of synaptic

structures called **glomeruli**. The mitral neurons connect to higher olfactory centers in the brain (Figure 23-39).

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

FIGURE 23-39 The anatomy of olfaction in the mouse. (a) Schematic representation of a sagittal section through an adult mouse head. Axons of the

olfactory receptor neurons (ORNs) in the main olfactory epithelium bundle to form the olfactory nerve and innervate the olfactory bulb. Each ORN of the main olfactory epithelium expresses only one odorant receptor gene. The vomeronasal organ and the accessory olfactory bulb are involved in pheromone sensing. (b) All of the ORNs that express a single type of receptor send their axons to the same glomerulus. In this figure, each color represents the neural connections for each distinct expressed receptor. The glomeruli are located in the olfactory bulb near the brain; in the glomeruli, the ORNs synapse with mitral neurons; each mitral neuron has its dendrites localized to a single glomerulus and its corresponding ORNs, thus carrying information about a particular odorant to higher centers of the brain. Each glomerulus thus receives innervation from sensory neurons expressing a single odorant receptor, providing the anatomical basis of the olfactory sensory map. See T. Komiyama and L. Luo, 2006, *Curr. Opin. Neurobiol.* **16**:67–73; and S. DeMaria and J. Ngai, 2010, *J. Cell Biol.* **191**:443.

Humans vary markedly in their ability to detect certain odors. For example, some cannot detect the steroid androstenone, a compound derived from testosterone and found in human sweat. Some describe the odor as pleasant and musky, while others compare it to the smell of dirty socks. These differences are all ascribed to inactivating missense mutations in the gene encoding the single androstenone GPCR. Individuals with two copies of the wild-type allele perceive androstenone as unpleasant, whereas those possessing one or no functional alleles perceive androstenone as less unpleasant or undetectable.

Despite the vast number of olfactory receptors, all generate the same intracellular signals through activation of the same trimeric G protein: $G_{\alpha olf} \cdot G_{\beta\gamma}$ (see Figure 23-37). $G_{\alpha olf}$ is expressed mainly in

olfactory neurons. Like $G_{\alpha}s$, the active $G_{\alpha olf}$·GTP formed after ligand binding activates an adenylyl cyclase that leads to the production of cyclic AMP (cAMP; see Figure 15-20). Two downstream signaling pathways are activated by cAMP. It binds to a site on the cytosolic face of a cyclic nucleotide–gated (CNG) Na^+/Ca^{2+} channel, opening the channel and leading to an influx of Na^+ and Ca^{2+} and local depolarization of the cell membrane. This odorant-induced depolarization in the olfactory dendrites spreads throughout the neuronal membrane, resulting in opening of voltage-gated Na^+ channels in the axon hillock and the generation of action potentials. Molecules of cAMP also activate protein kinase A (PKA), which phosphorylates and thus regulates transcription factors and other intracellular proteins.

Each Olfactory Receptor Neuron Expresses a Single Type of Odorant Receptor

The key to understanding the specificity of the olfactory system is that in both mammals and insects each ORN produces only a single type of odorant receptor. Any electrical signal from that cell will convey to the brain a simple message: “an odorant is binding to my receptors.” Receptors are not always completely monospecific for odorants. Some receptors can bind more than one kind of molecule,

but the molecules detected are usually closely related in structure. Conversely, some odorants bind to multiple receptors.

There are about 5 million ORNs in the mouse, so on average each of the 800 or so olfactory receptor genes is active in approximately 6000 cells. There are about 2000 glomeruli (roughly 2 for each odorant receptor gene), so on average the axons from a few thousand ORNs converge on each glomerulus (see Figure 23-39). From there, about 25 mitral axons per glomerulus, or a total of 50,000 mitral neurons, connect to higher brain centers. Thus the initial odorant-sensing information is carried directly to higher parts of the brain without processing, a simple report of what odorant has been detected.

The one neuron–one receptor rule extends to *Drosophila*. Detailed studies have been done in larvae, where a simple olfactory system with only 21 ORNs uses about 10–20 olfactory receptor genes. It appears that a unique receptor is expressed in each ORN, which sends its projections to one glomerulus. ORNs can send either excitatory or inhibitory signals from their axon termini, probably in order to distinguish attractive versus repulsive odors. Similar to mammals, the axons from the ORNs end in the glomeruli, which in flies are located in the antennal lobe of the larval brain. The research in *Drosophila* began with tests of which odorants bind to which receptors (Figure 23-40a). Some odorants are detected by a single receptor, some by several, so the combinatorial pattern allows many more odorants to be distinguished than just the

number of different olfactory receptors. The small total number of neurons has allowed a map to be constructed showing which odorants are detected by every glomerulus (Figure 23-40b). One striking finding was that glomeruli located near each other respond to odorants with related chemical structures: for example, linear aliphatic compounds or aromatic compounds. The arrangement may reflect evolution of new receptors concomitant with a process of subdivision of the olfactory part of the brain.

EXPERIMENTAL FIGURE 23-40 Individual olfactory receptor types can be experimentally linked to various odorants and traced to specific glomeruli in the *Drosophila* larval olfactory system. (a) The different olfactory receptor proteins are listed across the top, and the 27 odorants tested are shown down the left side. Colored dots indicate strong odor responses. Note that some odorants stimulate multiple receptors (e.g., pentyl acetate), while others (e.g., ethyl butyrate) act on only a single receptor. Note that many receptors, such as Or42a or Or67b, respond primarily to aliphatic compounds, whereas others, such as Or30a and Or59a, respond to aromatic compounds. (b) Spatial map of olfactory information in glomeruli of the *Drosophila* larval brain. The mapping was done by expressing a reporter gene under the control of each of the selected ORNs. The micrograph indicates the glomeruli that receive projections from ORNs producing each of the 10 indicated receptor protein types (Or42a, etc.). Also indicated are the odorants to which each receptor responds strongly. Note that, in this study, with one exception (Or30a and Or45b) each glomerulus has unique sensory capacities. Glomeruli-sensing odorants that are chemically similar tend to be situated next to one another. For example, the three glomeruli indicated by a blue solid line sense linear aliphatic compounds; those with yellow dashed lines, aromatic compounds.

[Part (b) republished with permission from Elsevier, from S. A. Kreher, J. Y. Kwon, and J. R. Carlson, 2005, “The Molecular Basis of Odor Coding in the

Drosophila Larva," *Neuron* **46**(3):445–456; permission conveyed through Copyright Clearance Center, Inc.]

The simple system of having each cell make only one receptor type also has some impressive difficulties to overcome: (1) Each receptor must be able to distinguish a type of odorant molecule or a set of molecules with specificity adequate to the needs of the organism. A receptor stimulated too frequently would not be useful. (2) Each cell must express one and only one receptor gene product. All the other receptor genes must be turned off. At the same time, the collective efforts of all the cells in the nasal epithelium must allow the production of enough different receptors to give the animal adequate sensory versatility. It does little good to have genes for hundreds of receptors if most of them are never expressed, but it is a regulatory challenge to turn on one and only one gene in each cell and at the same time express all the receptor genes across the complete population of cells. (3) The neuronal wiring of the olfactory system must make discrimination among odorants possible so that the brain can determine which odorants are present. Otherwise the animal might be feeling at ease and relaxed when it should be running away as fast as possible.

The solution to the first problem is the great variability of the olfactory receptor proteins, both within and between species. The solution to the second problem, the expression of a single olfactory receptor gene per cell, has been shown to involve a remarkable form of epigenetic silencing that assures that thousands of olfactory

receptor alleles remain inactive in each ORN. These studies have shown that receptor choice relies on the selective activation of a single olfactory receptor gene from a developmental state in which all olfactory receptor genes are silenced. Activation is triggered by a histone demethylase and a specific adenylate cyclase, both of which are required to derepress the single olfactory receptor locus. The active and inactive genes are spatially segregated within the nucleus, with the inactive genes being buried in heterochromatic foci while the active genes are located in euchromatic domains (see Chapter 8).

The third problem, how the system is wired so the brain can understand which odor has been detected, has been partly answered. First, ORNs that express the same receptor send their axons to the same glomerulus. Thus all cells that respond to the same odorant send processes to the same destination. In mice, a crucial clue about the patterning of the olfactory system came from the discovery that olfactory receptors play two roles in ORNs: odorant binding and, during development, axon guidance. Multiple ORN axons expressing the same receptor are guided to the same glomerulus destination. Each olfactory receptor has a distinct, odorant-independent level of activation that turns on adenylate cyclase, with the varying levels of cAMP turning on CREB-dependent expression of standard axon-guidance molecules, whose graded activity is used to specify targeting to a specific glomerulus.

KEY CONCEPTS OF SECTION 23.4

Sensing the Environment: Touch, Pain, Taste, and Smell

- Mechanoreceptors and pain receptors are gated Na^+ or Na^+/Ca^{2+} channels. They are present on specialized terminals at the end of sensory neurons and convey afferent information to the spinal cord and brain stem.
- Touch sensitivity requires several cytoskeletal and extracellular matrix proteins as well as a gated Na^+ channel (see Figure 23-33).
- Piezo 1 and 2 are large-channel proteins that convert mechanical stimulus directly into cation conductance (see Figure 23-34).
- TRPV channels are nociceptors that are activated by a variety of stimuli, including heat and capsaicin. Their molecular structure is similar to the structure of voltage-gated ion channels and was recently solved by single particle cryoEM (see Figure 23-35).
- Five primary tastes are sensed by subsets of cells in each taste bud. Salty and sour tastes are detected by specific ion channel proteins, and G protein–coupled receptors detect sweetness, umami, and bitterness.
- In all cases, tastants lead to membrane depolarization and secretion of small molecules such as ATP that stimulate the adjacent neurons.
- Taste is represented in a topographic map in a part of the cortex called the *insula*. Activation of taste receptors by a specific type of taste (e.g., sweet or salty) activates neurons in specific, nonoverlapping regions of the insula.
- Odorant receptors, which are seven-transmembrane G protein–coupled receptors, are encoded by a very large set of genes. Any one olfactory receptor neuron expresses one and only one olfactory receptor gene, so a signal from that cell to the brain unambiguously conveys the nature of the chemical sensed.
- Olfactory receptor neurons (ORNs) that express the same receptor gene send their axons to the same glomerulus, and projection nerves (mitral neurons in mammals) carry odorant-specific information from the glomeruli to the brain (see Figures 23-38, 23-39, and 23-40).

23.5 Forming and Storing Memories

One of the most remarkable features of the brain is its capacity to form and store memories. Decades of research have revealed that memories are stored as changes in the strength and number of connections that form between neurons. While the overall structure of the nervous system is genetically hardwired, neural circuits undergo extensive sculpting and rewiring in response to a variety of stimuli. This process of experience-dependent changes in synaptic connectivity is called **synaptic plasticity**. By modifying brain wiring in response to experiences, synaptic plasticity provides a biological means of integrating nature and nurture to determine our identities.

Memories Are Formed by Changing the Number or Strength of Synapses Between Neurons

The concept of synaptic plasticity has a long history, beginning with the neuroanatomical studies of Santiago Ramón y Cajal at the turn of the nineteenth century. He used a method called the *Golgi stain* to visualize individual neurons in the brains of humans and other animals (Figure 23-41a). The Golgi stain was developed by the Italian scientist Camillo Golgi, with whom Ramón y Cajal shared the 1906 Nobel Prize in Physiology or Medicine for their work on the structure of the nervous system. While Golgi believed that the brain

consisted of a “reticular network,” a large syncytium of interconnected nerve cells, Ramón y Cajal recognized that the brain consisted of individual neurons that interacted with one another at sites of contact — what we now know of as synapses. Ramón y Cajal detected synapses as small dendritic protuberances. These protuberances are the postsynaptic compartments of excitatory synapses and can be visualized not only with the Golgi stain but also with more modern methods based on genetic expression of fluorescent proteins (Figure 23-41b). Based on his histological data, Ramón y Cajal hypothesized that memories were stored in the brain by changing the structure of the neuronal arbor and by changing the structure and number of synapses that formed between neurons. In poetic terms, Ramón y Cajal speculated that: “the cerebral cortex is like a garden full of innumerable trees, the pyramidal cells, which in response to intelligent cultivation can increase the number of their branches … and produce ever more varied flowers and fruit.”

FIGURE 23-41 Visualizing dendritic spines. (a) Santiago Ramón y Cajal used the Golgi staining method to visualize individual neurons in the cerebellum of a pigeon in 1899. This method permitted Ramón y Cajal to visualize individual neurons in the brain; the tissue is densely packed with neurons but the Golgi stain only labels sparse neurons in the tissue. The postsynaptic compartment of excitatory synapses consists of a spiny protuberance from the dendrite, called a *spine*. Ramón y Cajal detected these spines in neurons (here in the Purkinje neurons of the cerebellum). In modern-day approaches, fluorescent proteins can be delivered using a microelectrode or expressed genetically to allow visualization of a single neuron in tissue. (b) A fluorescent dye is delivered to the cell body of a single Purkinje neuron in mouse cerebellum by a microelectrode (*right*) and is visualized by two-photon microscopy. The fluorescence is yellow in the cell body and orange-red in the dendrites. At higher resolution, we can image spine dynamics using time-lapse microscopy and in this way directly demonstrate changes in synaptic connectivity with experience. In this image, a second, larger electrode (*left*) filled with a red fluorescent dye (with yellow precipitates within the electrode) is used to electrically stimulate synapses forming onto the labeled neurons.

Decades of research have largely validated Ramón y Cajal's predictions, although memories are now thought to be stored

primarily as changes in the synapses ("flowers and fruit") rather than by changes in dendrites and axons ("branches"). Studies of the gill-withdrawal reflex in the sea slug *Aplysia californica* provide a classic demonstration of the structural basis of memory storage (Figure 23-42). *Aplysia californica* is a useful model organism for studying the cell biology of memory because its nervous system is relatively simple and its neurons are very large and identifiable, which means that the same neuron can be identified from one animal to another. These features allowed Nobel laureate Eric Kandel and his colleagues to delineate the neural circuitry underlying specific behaviors in the animal and to then determine how the synaptic connections between neurons in this circuit changed during memory formation. They focused on a simple reflexive behavior, the siphon gill-withdrawal reflex, in which touching the animal's siphon (a tubelike anatomical structure through which water flows) leads to a defensive withdrawal of its respiratory organ, the gill. Sensory neurons from the siphon that synapse onto motor neurons to the gill mediate the reflex. Touching the siphon triggers firing of the sensory neuron, which triggers an action potential in the motor neuron, which in turn synapses on the gill muscle and causes it to contract. The reflex can be either strengthened or weakened by experience. Repeated touching of the siphon leads to a decrease in the amplitude of the gill-withdrawal reflex, called *habituation*. In contrast, presentation of a noxious stimulus like delivery of an electric shock to the tail leads to an increase in the amplitude of the gill-withdrawal reflex, called

sensitization. Sensitization can be thought of as a form of fear learning. Habituation and sensitization can be transient or long lasting, depending on the strength and duration of the stimulus. Long-lasting forms of habituation and sensitization were found to involve dramatic decreases and increases, respectively, in the number of connections that formed between sensory and motor neurons. In this way, just as Ramón y Cajal predicted, the animal's experience changed the wiring of its nervous system, thereby encoding a memory and changing the animal's behavior.

FIGURE 23-42 Long-term memories are stored as changes in synaptic connectivity. (a) The sea slug *Aplysia californica* is a model system for studying the cell biology of synaptic plasticity and memory. Tactile stimulation of the siphon (a tubelike structure through which water flows) stimulates the gill-withdrawal reflex. In habituation, the siphon is repeatedly touched, which habituates the animal to this stimulation and reduces the amplitude of the gill

withdrawal. In sensitization, the animal receives a noxious stimulus like a tail shock, which sensitizes the reflex so that the gill-withdrawal amplitude is enhanced. (b) Three-dimensional reconstructions of siphon sensory neurons from control animals and from animals that have undergone long-term sensitization of the gill-withdrawal reflex. Notice the expansion of the sensory neuron branches after sensitization. The growth of neuronal processes is accompanied by a growth of new synaptic connections between the sensory and motor neurons. (c) Illustrations showing the changes in connectivity that occur during plasticity of the gill-withdrawal reflex. Sensitization is accompanied by the growth of new connections between the sensory and motor neuron, while habituation is accompanied by a decrease in the number of connections between the sensory and motor neuron.

[Part (b) from C. H. Bailey and M. Chen, 1988, "Long-Term Memory in Aplysia Modulates the Total Number of Varicosities of Single Identified Sensory Neurons," *Proc. Nat'l Acad. Sci. USA* **85**:2373–2377.]

The Hippocampus Is Required for Memory Formation

Studies in *Aplysia* and in other model organisms, including *Drosophila* and mice, have begun to reveal many of the molecular mechanisms underlying experience-dependent synaptic plasticity. Clinical studies in humans as well as experimental studies in animals have shown that the hippocampus is required for the formation of long-term memories. Humans and animals with lesions in their hippocampus can form short-term memories and maintain their old memories but are no longer able to form new long-term memories. Not only is the hippocampus critical for long-

term memory formation, but its anatomy also makes it especially suitable for electrophysiological studies of synaptic connectivity. As shown in Figure 23-43, the hippocampus consists of three sequential pathways (perforant, mossy fiber, and Schaffer collateral pathways), each with discrete cell-body layers and axonal and dendritic projections. High-frequency stimulation of the axons of presynaptic neurons in each of these pathways produces a long-lasting strengthening of the connections onto the postsynaptic neurons, called *long-term potentiation (LTP)*, while low-frequency stimulation produces a long-lasting weakening of the connections, called *long-term depression (LTD)*.

FIGURE 23-43 Synaptic plasticity in the mouse hippocampus: long-term potentiation (LTP) and long-term depression (LTD), and roles for regulated trafficking of AMPA glutamate receptors. (a) The mouse hippocampus can be dissected from mouse brain cut into transverse slices, preserving the three sequential synaptic pathways, from the entorhinal cortex (not shown) to the dentate gyrus (DG), the DG to CA3, and CA3 to CA1. Electrodes can be used to stimulate axonal afferents and record from postsynaptic follower cells, as illustrated for the Schaffer collateral (CA3-CA1) pathway. (b) Trains of low-frequency stimulation or high-frequency stimulation to the axonal fibers produce sustained decreases or increases in synaptic strength, which are measured as the postsynaptic response to a test stimulus. These tracings show the strength of the synaptic connection on the *y* axis, with time on the *x* axis. The dotted line shows the baseline strength of the connections, which are decreased by low-frequency stimulation and increased by high-frequency stimulation. These forms of plasticity are known as *long-term depression (LTD)* and *long-term potentiation (LTP)*. (c) In the basal state, AMPA receptors (black) traffic constitutively to and from the plasma membrane of the postsynaptic compartment via recycling endosomes. Receptors are delivered to the plasma membrane lateral to the postsynaptic density via exocytosis and are internalized by clathrin-mediated endocytosis into recycling endosomes. In the postsynaptic density, the AMPA receptors are stabilized by interactions with proteins, including transmembrane AMPA receptor regulatory proteins (TARPS, not shown). Following induction of LTD of glutamatergic synapses, there is an increase in the diffusion of AMPA receptors out of the postsynaptic density and in their internalization into recycling endosomes. This results in a decrease in the number of AMPA receptors on the postsynaptic membrane and a decrease in the postsynaptic response to a given amount of glutamate release from the presynaptic neuron. Following induction of LTP at glutamatergic synapses, there is an increase in the exocytosis of AMPA receptors and an increase in their diffusion into the postsynaptic density. This results in an increase in the number of AMPA receptors on the postsynaptic membrane and an increase in the postsynaptic response to a given amount of glutamate release from the presynaptic neuron. Regulated trafficking of AMPA receptors provides one molecular mechanism underlying the activity-dependent changes in synaptic strength that accompany synaptic plasticity and memory. See V. M. Ho, J.-A. Lee, and K. C. Martin, 2011, *Science* **334**:623–628; and J. D. Shepherd and R. L. Huganir, 2007, *Annu. Rev. Cell Dev. Bi.* **23**:613–643.

While a multitude of studies have shown correlations between LTP, LTD, and memory, more recent optogenetic studies succeeded in demonstrating a causal role for synaptic plasticity in producing memories. To do this, the investigators expressed channelrhodopsin in hippocampal neurons in mice and stimulated the neurons with light to induce LTP. Induction of LTP caused the mice to acquire a false memory in which they demonstrated fear to an environment even though they had never encountered a frightening stimulus in that environment!

Multiple Molecular Mechanisms Contribute to Synaptic Plasticity

In considering how experience can change synaptic strength, it is useful to think about the structure of the chemical synapse and the process of synaptic transmission described in Section 23.3. Long-lasting changes in plasticity have been shown to involve presynaptic changes in neurotransmitter release, trans-synaptic adhesion, and postsynaptic responses to neurotransmitter. We will briefly touch on pre- and trans-synaptic mechanisms and then delve into slightly more detail on postsynaptic mechanisms, which have been studied in greater depth.

Experiences that stimulate hippocampal neurons trigger elevations in intracellular calcium, which in turn activates kinases that

phosphorylate synapsins, the molecules that organize synaptic vesicles into discrete pools within the presynaptic compartment. This phosphorylation of synapsins increases the number of synaptic vesicles available for release, thereby increasing the amount of neurotransmitter that is released with a given stimulus. Experience also activates kinases that phosphorylate RIM, the molecule that tethers voltage-gated Ca^{2+} channels to the release machinery, and this phosphorylation is required for LTP of hippocampal synapses.

Synaptic plasticity also depends on activation of kinases in the postsynaptic compartment. Influx of Ca^{2+} through voltage-gated Ca^{2+} channels and specific glutamate receptors in the postsynaptic membrane activates one particularly important kinase, the calcium-calmodulin-dependent kinase IIα (CaMKIIα; see Chapter 15 for discussion of calcium calmodulin signaling). This kinase has the special property that once activated, it can remain persistently activated even in the absence of stimulation. This is because once activated, CaMKIIα autophosphorylates itself, which renders it constitutively active for about 30 minutes, during which time the kinase phosphorylates many substrates in the postsynaptic compartment, including glutamate receptors. Mice lacking CaMKIIα have deficits in both LTP in the hippocampus and in memory formation.

As discussed in Chapter 15, the sensitivity of a cell to external signals is determined by the number of surface receptors. In line

with this concept, one of the best characterized mechanisms underlying synaptic plasticity involves activity-dependent changes in the number of glutamate receptors that are present in the postsynaptic membrane. This process has been especially well studied in the context of hippocampal LTP and LTD (Figure 23-43c). One of the major classes of glutamate receptors, called *AMPA receptors*, traffic constitutively to and from the plasma membrane via recycling endosomes. AMPA receptors are delivered by exocytosis at extrasynaptic sites and then laterally diffuse into the postsynaptic density, the protein-dense region of the postsynaptic site that faces the synaptic cleft and thus receives neurotransmitters released by the presynaptic terminal. AMPA receptors are removed by endocytosis, which occurs when the receptors diffuse laterally to extrasynaptic sites and are then internalized by clathrin-mediated, dynamin-dependent endocytosis.

While AMPA receptor trafficking occurs under basal conditions, it is modulated by activity through changes in actin and myosin dynamics as well as AMPA receptor interactions with scaffolding proteins and accessory subunits. One of these accessory subunits, *Stargazin*, mediates the interaction between AMPA receptors and the postsynaptic density protein PSD95. This interaction is critical to the localization of AMPA receptors at the synapse, since interaction with PSD95 stabilizes AMPA receptor localization within the postsynaptic density. Activity causes the phosphorylation of Stargazin, decreasing the mobility of AMPA receptors and increasing their concentrations

at the synapse. Blocking Stargazin phosphorylation or de-phosphorylation blocks hippocampal LTP and LTD, respectively. Stargazin is one of a family of *transmembrane AMPA receptor regulatory proteins (TARPs).* TARPs bind to all AMPA receptor subunits, are differentially expressed throughout the brain, and mediate the delivery of AMPA receptors to the surface and synapse of neurons.

Formation of Long-Term Memories Requires Gene Expression

The mechanisms described above are especially important for short-term forms of plasticity that underlie short-term memories. While the formation of short-term plasticity, and short-term memory, have been shown to rely on modifications of preexisting proteins at the synapse, the formation of long-term memories differs in that it depends upon new gene expression. This can be thought of in the context of the different effects of extracellular stimulation that were discussed in Chapter 15: stimuli can produce short-term changes by altering the activity of preexisting enzymes and proteins in the cell, or long-term functional changes by altering the expression of genes in the cell (see Figure 15-3). Studies in many systems and species, including in rodent hippocampus, have demonstrated that LTP and LTD can be divided into transient forms of plasticity that do not require gene expression and *l*ong-lasting

forms (L-LTP and L-LTD) that require both mRNA and protein synthesis.

The extreme morphological polarity and compartmentalization of neurons adds significant challenges to stimulus-induced changes in gene expression. First, to turn on transcription, signals must be relayed to the nucleus from the synapse, which in many cases is located at great distances from the cell body. Neurons are specialized for rapid signaling between compartments by electrical signaling. However, many studies have also shown that signaling molecules, including kinases, phosphatases, and transcriptional regulators, are actively transported from stimulated synapses to the nucleus to regulate transcription. In most cases, this long-distance retrograde transport has been shown to involve dynein motor protein–mediated transport along microtubules (as described in Chapter 18). How signaling is faithfully maintained during this long-distance transport in order to couple synaptic stimulation with gene expression is an area of active research.

The second great challenge in understanding the mechanism of stimulus-induced gene expression during synaptic plasticity derives from the fact that each neuron has a single nucleus and yet can form thousands of synapses. Long-lasting forms of synaptic plasticity are often synapse-specific, that is, they involve changes in synaptic strength at some but not all synapses formed by a single neuron. Since long-term plasticity requires transcription, synapse specificity begs the question of how gene expression can be spatially regulated

in such a highly compartmentalized cell. One important mechanism involves the localization of mRNAs and their local translation in response to synaptic stimulation, as was discussed in Chapter 9. Indeed, L-LTP of hippocampal synapses has been shown to require the translation of mRNAs that are localized in dendrites and at synapses. Electron micrographic studies have identified polyribosomes, actively translating ribosomes, at the base of spines in hippocampal neurons and have further shown that the number of spines controlling polyribosomes greatly increases after induction of L-LTP. Together, these studies have focused attention on the importance of post-transcriptional gene regulation in neurons during synaptic plasticity and on a host of questions about mRNA localization and regulated translation: What mRNAs are localized to synapses? How are they localized? How is their translation regulated by synaptic activity? What is the specific function of the locally translated protein? Why are some mRNAs translated into protein in the neuronal cell body and then transported to synapses, and others translated directly at synapses?

Indicative of the importance of post-transcriptional gene regulation in the proper functioning of the nervous system, mutations in an RNA-binding protein, the fragile X mental retardation protein, FMRP, cause a common form of mental retardation, fragile X syndrome (FXS). Mutations in the gene encoding FMRP, the *fmr1* gene, constitute the most common single-gene cause of autism. The most common mutations that lead to FXS

are expansions of CGG repeats in the *fmr1* gene that leads to gene methylation and silencing, as was described for Huntington's disease in Chapter 6. FMRP is a translational repressor that binds target mRNA and prevents its translation. A population of FMRP localizes to the base of dendritic spines, where it is thought to maintain mRNAs in a dormant state until synaptic stimulation triggers their translation. Genetically modified mice that lack FMRP serve as remarkably good models for the human disease. The mice show deficits in learning, reflective of the intellectual disability in FXS patients. Both mice and humans have abnormalities in the structure of their synaptic spines, which are elongated, like immature spines, rather than stubby, like mature spines. Studies in the mouse have revealed excessive basal translation of mRNAs at synapses and have further shown alterations in protein-synthesis-dependent forms of hippocampal LTD. Together, these findings indicate that synaptic translation of localized mRNAs is critical to the formation and the experience-dependent plasticity of neural circuits and that alterations in this process are a cause of neurodevelopmental and cognitive disorders. ■

KEY CONCEPTS OF SECTION 23.5

Forming and Storing Memories

- Experience changes the number and strength of connections between neurons in the brain through a process known as *synaptic plasticity*. Synaptic plasticity provides a biological basis for the formation and storage of memories.
- Studies of habituation and sensitization demonstrate that learning produces changes in synaptic connectivity. Experiments looking at the gill-withdrawal reflex in marine

mollusk *Aplysia californica* show that habituation involves decreases in the connectivity of the sensory and motor neurons that give rise to the gill-withdrawal reflex, while sensitization involves increases in sensory-motor connectivity (see Figure 23-42).

- The hippocampus is a region of the brain that is required for the formation of long-lasting memories (see Figure 23-43). Hippocampal synapses undergo activity-dependent forms of synaptic strengthening called *long-term potentiation (LTP)* and activity-dependent forms of synaptic weakening called *long-term depression (LTD)*.
- Changes in synaptic strength can be mediated by presynaptic, trans-synaptic, or postsynaptic mechanisms.
- Activity generates a constitutively active form of CaMKIIα in the postsynaptic compartment, which phosphorylates substrates in the postsynaptic density, including glutamate receptors, leading to changes in synaptic strength.
- Activity regulates the trafficking of AMPA glutamate receptors in the postsynaptic membrane. LTP is accompanied by an increase in insertion of AMPA receptors in the postsynaptic density, while LTD is accompanied by a decrease in the concentration of AMPA receptors in the postsynaptic density (see Figure 23-43c).
- Short-term forms of synaptic plasticity involve modifications of preexisting proteins at the synapses, but long-term forms require new mRNA and protein synthesis.
- Synapse-specific forms of plasticity involve the local translation of synaptically localized mRNAs.
- Fragile X syndrome is caused by null mutations in the gene encoding the RNA-binding protein FMRP. FMRP regulates local translation at synapses. Mice lacking FMRP have abnormal synapses and exhibit learning impairments and deficits in hippocampal LTD.

voltage-gated channels

Review the Concepts

1. What is the role of glial cells in the brain and other parts of the nervous system?
2. The resting potential of a neuron is approximately −70 mV inside compared with outside the cell. How is the resting potential maintained in animal cells?
3. Name the three phases of an action potential. Describe for each the underlying molecular basis and the ion involved. Why is the term "voltage-gated channel" applied to Na^+ channels involved in the generation of an action potential?
4. Explain how the crystal structures of potassium ion channels suggest the way in which the voltage-sensing domains interact with other parts of the proteins to open and close the ion channels. How does this structure-function relationship apply to other voltage-gated ion channels?

5. Explain why the strength of an action potential doesn't decrease as it travels down an axon.
6. Explain why the membrane potential does not continue to increase but rather plateaus and then decreases during the course of an action potential.
7. What does it mean to say that action potentials are "all or none"?
8. What prevents a nerve signal from traveling "backward" toward the cell body?
9. Why is the cell unable to initiate another action potential if stimulated during the refractory period?
10. Myelination increases the velocity of action potential propagation along an axon. What is myelination? Myelination causes clustering of voltage-gated Na^+ channels and Na^+/K^+ pumps at nodes of Ranvier along the axon. Predict the consequences to action potential propagation of increasing the spacing between nodes of Ranvier by a factor of 10.
11. Describe the mechanism of action for addictive drugs such as cocaine.
12. Acetylcholine is a common neurotransmitter released at the synapse. Predict the consequences for muscle activation of decreased acetylcholine esterase activity at nerve-muscle synapses.
13. Describe the ion dynamics of the muscle-contraction process.
14. Following the arrival of an action potential in stimulated cells, synaptic vesicles rapidly fuse with the presynaptic

membrane. This happens in less than 1 ms. What mechanisms allow this process to take place at such great speed?

15. Neurons, particularly those in the brain, receive multiple excitatory and inhibitory signals. What is the name of the extension of the neuron at which such signals are received? How does the neuron integrate these signals to determine whether or not to generate an action potential?
16. Explain the mechanism by which action potentials are prevented from being propagated to a postsynaptic cell if transmitted across an inhibitory synapse.
17. What is the role of dynamin in recycling synaptic vesicles? What evidence supports this?
18. Compare and contrast electrical and chemical synapses.
19. Compare the structures and functions of the receptor molecules for salty and sour taste; the taste-receptor molecules for sweetness, bitterness, and umami; and odor-receptor molecules.
20. Describe a synaptic mechanism underlying the formation of memory.

CHAPTER 24

Immunology

Courtesy of M. Boes and H. L. Ploegh.

Dendritic cells in the skin have class II MHC molecules on their surface. Those shown here were engineered to express a class II MHC–GFP fusion protein, which fluoresces green.

OUTLINE

24.1 Overview of Host Defenses
24.2 Immunoglobulins: Structure and Function
24.3 Generation of Antibody Diversity and B-Cell Development
24.4 The MHC and Antigen Presentation
24.5 T Cells, T-Cell Receptors, and T-Cell Development
24.6 Collaboration of Immune-System Cells in the Adaptive Response

---

Metazoan animals and the cells within them are surrounded by a sea of pathogens — viruses, bacteria, and fungi — and have evolved a number of defenses to counter them, collectively termed the *immune system*. **Immunity** is a state of protection against the harmful effects of exposure to pathogens. Even insects such as *Drosophila* have an immune system with two types of defenses: (1) physical barriers and chemical defenses, and (2) cells that comprise an innate immune system that can recognize and destroy certain pathogens (Figure 24-1). Mechanical and chemical defenses operate continuously. Innate immune responses, which involve cells and molecules that are present in the body at all times, are rapidly activated (in minutes to hours). However, because they recognize molecules that are common to many foreign organisms, their ability to distinguish among different pathogens is somewhat limited.

FIGURE 24-1 The three layers of vertebrate immune defenses. *Left:* Mechanical defenses consist of epithelia and skin. Chemical defenses include the low pH of the gastric environment and antibacterial enzymes in tears. These barriers provide continuous protection against invaders. Pathogens must physically breach these defenses (step 1) to infect the host. *Middle:* Pathogens that have breached the mechanical and chemical defenses (step 2) are handled by cells and molecules of the innate immune system (blue). These include phagocytic cells (neutrophils, dendritic cells, macrophages) that engulf the invader and destroy it in lysosomes, natural killer (NK) cells, complement proteins, and certain interleukins (IL-1, IL-6). Innate defenses are activated within minutes to hours of infection. *Right:* In vertebrates, pathogens that are not cleared by the innate immune system are dealt with by the adaptive immune system (step 3), in particular B lymphocytes and their antibody products (Y-shaped icons), and several types of T cells and the many proteins they make that can destroy pathogens. Full activation of adaptive immunity requires days. The products of an innate response may potentiate an ensuing adaptive response (step 4). Likewise, the products of an adaptive immune response, including antibodies, may enhance innate immunity (step 5). Several cell types and secreted products are used in both the innate and adaptive immune systems and serve to connect these two layers of host defense.

In addition to these defense mechanisms, vertebrates have evolved a sophisticated immune system, the *adaptive immune system,* that can recognize and respond to many types of molecules not normally present in the body, including those that are parts of specific pathogens. The adaptive immune system generates secreted proteins termed *antibodies,* each of which binds to a specific foreign target molecule (see Figure 3-22). The adaptive immune system also generates many types of cells that attack and destroy pathogenic invaders. Adaptive immune responses take several days to develop fully and are highly specific; that is, they can distinguish between closely related pathogens based on very small molecular differences in the structures of their proteins or other polymers. The adaptive immune system makes adjustments to these threats over time, changing in response to the types and abundances of pathogens to which the host is exposed.

All pathogens have found ways to disarm the immune system or manipulate it to their own advantage, and host-pathogen interactions are an evolutionary work in progress. Virtually all pathogens have relatively short generation times compared with the hosts they infect and thus can evolve sophisticated countermeasures against their hosts' immune system. This explains why, despite the evolution of remarkably sophisticated adaptive immune systems, pathogenic viruses, bacteria, and parasites continue to pose a threat to human populations. Seasonal outbreaks of influenza caused by new strains of influenza virus are just one example.

These sophisticated defenses come at a price: an immune system capable of dealing with a massively diverse collection of rapidly evolving pathogens can sometimes mistake the host's own tissues for pathogens and mount an attack against its own cells and tissues, a phenomenon called *autoimmunity*. Even so, we have learned to exploit the workings of the immune system to create vaccines that protect against a variety of infectious diseases. Vaccines are remarkably cost effective and have contributed to eliminating the scourge of many epidemics, such as outbreaks of smallpox.

In this chapter, we deal mainly with the vertebrate immune system, with particular emphasis on those molecules, cell types, and pathways that uniquely distinguish the immune system from other types of cells and tissues. Four remarkable features characterize the vertebrate immune system. They are specificity, diversity, memory, and tolerance. Specificity is the immune system's ability to distinguish between closely related substances. **Diversity** is the system's capacity to specifically recognize an astoundingly large number ($>10^6$) of different molecules. **Memory** is a host's ability to recall previously experienced exposure to a foreign substance and more rapidly and effectively defend itself from that substance the next time it is encountered. **Tolerance** is the ability to avoid mounting an immune-system attack against the host's own cells and tissues; that is, the ability to distinguish the body's own tissues ("self") from foreign materials including pathogens ("nonself").

Any material that can evoke an immune response is referred to as an **antigen**. As we shall see, the immune system achieves specificity and diversity by generating a large number of distinct proteins, such as antibodies and specific cell-surface receptors, each of which can bind very tightly to a target antigen such as a pathogenic molecule, but not to other, perhaps structurally very similar, molecules.

Memory and tolerance depend on complex cellular systems. They are accomplished through the generation of a massively diverse set of cell-surface receptors that bind specific antigens. Cells that display these receptors have been "trained" so that they are largely unresponsive to self components (self-tolerant).

From a practical perspective, the powers of the immune system can be exploited therapeutically. Today there is a multibillion-dollar market for monoclonal antibodies, which are used in the treatment of inflammatory conditions, autoimmune diseases, and cancer. The molecules that constitute the adaptive immune system — antibodies in particular — are also indispensable tools for the cell biologist, as we saw in Chapters 3 and 4. Antibodies allow visualization and isolation of the molecules they recognize with pinpoint precision. Their ability to do so has been invaluable in the accurate description of the components that make up the cell and its organelles and their localization, both in cells and in tissues. The technique of *immunofluorescence*, for example, is widely used by cell biologists to study cell morphology and behavior, while *immunoblotting (Western*

blotting) has become an indispensable tool in the study of signal transduction.

The ways in which these foreign materials are recognized and eliminated involve molecular and cell biological principles unique to the immune system. We begin this chapter with a brief sketch of the organization of the mammalian immune system, introducing the essential cell players in innate and adaptive immune responses and describing inflammation, a localized response to injury or infection that leads to the activation of immune-system cells and their recruitment to the affected site. In the next two sections, we discuss the structure and function of **antibody** (or **immunoglobulin**) molecules, which bind to specific molecular features on antigens, and how variability in antibody structure contributes to the recognition of specific antigens. The enormous diversity of antigens that can be recognized by the adaptive immune system finds its explanation in unique rearrangements of segments of DNA to generate antigen-specific receptors in B and T lymphocytes, commonly called **B cells** and **T cells**, which are the white blood cells that carry out antigen recognition. These gene rearrangements permit adaptation to a wide variety of pathogens by setting the specificity of antigen-binding receptors on lymphocytes; they also determine cell fate in the course of lymphocyte development.

Although the gene rearrangement mechanisms that give rise to antigen-specific receptors on B and T cells are very similar, the manner in which these receptors bind to (recognize) antigens is very different. The receptors on B cells — antibody molecules anchored in the plasma membrane — can interact with intact antigens directly, but the receptors on T cells cannot. Instead, as described in Section 24.4, the receptors on T cells recognize forms of antigen that are processed by target cells: small peptides and other small molecules that are displayed (or "presented") on the surfaces of these cells by specialized cell-surface glycoproteins. These glycoproteins are encoded by genes in a region of the genome called the **major histocompatibility complex (MHC)**. These MHC-encoded glycoproteins, also called *MHC products*, help determine the host's ability to mount both T-cell and B-cell responses to antigens.

Understanding these fundamental properties of the immune system has allowed us to answer a number of very practical questions: How can we best make antibodies that afford protection against an infectious agent? How can we raise antibodies to specific proteins we want to study in the laboratory? Knowledge of antigen processing and presentation thus informs both vaccine design to protect against infectious disease and the generation of tools essential for research. MHC-encoded glycoproteins also play a key role in an individual's development of tolerance for his or her own antigens. We conclude the chapter with an integrated view of the immune response to a pathogen, highlighting the collaboration between

different immune-system cells that is required for an effective immune response.

24.1 Overview of Host Defenses

Because the immune system evolves in the presence of microbes, including pathogenic ones, we begin our overview of host defenses by examining where typical pathogens are found in a host and where they replicate. Then we introduce the basic concepts of innate and adaptive immunity, including some of the key cellular and molecular players.

Pathogens Enter the Body Through Different Routes and Replicate at Different Sites

Human skin has a surface area of some 20 square feet. The epithelial surfaces that line our airways, gastrointestinal tract, and urogenital tract present an even more formidable surface area of about 4000 square feet. All these surfaces are exposed on a daily basis to viruses, bacteria, and fungi in the environment. Some of these bacteria, called *commensal bacteria*, do not usually cause disease and in fact can be beneficial, helping to provide key nutrients or to maintain healthy skin. The microbiota also helps tune reactivity and composition of both the innate and adaptive immune systems via engagement of their receptors and the release of small molecules. It is thought that at any point in time, an adult human may be carrying as much as 3 pounds of microbes, against

which most of us do not develop an overt inflammatory immune reaction. These commensal microbes are not pathogenic as long as they remain on these outer surfaces of the body. If the normal barrier function of the epithelia that compose these surfaces is compromised, however, and these microbes enter the body, they can be pathogenic. Food-borne pathogens and sexually transmitted agents target the epithelia to which they are exposed. The sneeze of a flu-infected individual releases millions of virus particles in aerosolized form, ready for inhalation by a new host. Rupture of the skin, even if only by minor abrasions, or of the epithelial barriers that protect the underlying tissues provides an easy route of entry for pathogens, which then gain access to a rich source of nutrients (for bacteria) and to the cells required for replication (for viruses).

Replication of viruses is confined strictly to the cytoplasm or nuclei of host cells, where viral protein synthesis and replication of the viral genetic material occur. Viruses can then spread to other cells either as free virus particles (virions) released from the initially infected cell or by direct transfer to an adjacent cell (cell-to-cell spreading). Many bacteria can replicate in the extracellular spaces of the body, but some are specialized to invade host cells and survive and reproduce within those cells. Such intracellular bacteria, such as *Mycobacterium tuberculosis,* the causative agent of tuberculosis, reside either in the membrane-delimited vesicles through which they enter cells by endocytosis or phagocytosis (see Figure 17-19) or in the cytoplasm if they escape from these vesicles. An effective host

defense system, therefore, needs to be capable of eliminating not only extracellular viruses and bacteria, but also host cells that harbor pathogens.

Parasitic eukaryotes can also cause disease. Some of these parasites, such as the protozoans that cause sleeping sickness (trypanosomes) or malaria (*Plasmodium* species; see Figure 1-25), have very complex life cycles and have evolved complex countermeasures to avoid destruction by the host's immune system.

Cells of the Innate and Adaptive Immune Systems Circulate Throughout the Body and Take Up Residence in Tissues and Lymph Nodes

The circulatory system (Figure 24-2) is responsible for moving blood throughout the body. Blood comprises cells (red and white blood cells, platelets) and liquid (plasma, which contains dissolved substances including proteins, ions, and small molecules). In addition to the hemoglobin-containing, oxygen-carrying erythrocytes (red blood cells) that compose the overwhelming majority of blood cells, the blood also contains *leukocytes* (white blood cells) and platelets (involved in blood clotting). Leukocytes encompass a variety of cell types, including lymphocytes (B and T cells), monocytes (precursors to the scavenger cells called

macrophages), dendritic cells, neutrophils, and natural killer (NK) cells, all of which have distinct functions in the immune system. In contrast to erythrocytes, which never leave the circulation until they get old and die, leukocytes leave the circulation and enter target tissues to help protect the body from invaders. The circulatory system moves leukocytes from the sites where they are generated (bone marrow, thymus, fetal liver) to the sites where they can be activated (lymph nodes, spleen), and then to the site of infection. Once leukocytes arrive at a given location, they may leave and re-enter the circulation in the course of their tasks.

FIGURE 24-2 The circulatory and lymphatic systems. Positive arterial pressure exerted by the pumping heart is responsible for the movement of liquid from the circulatory system (red) into the interstitial spaces of the tissues, so that all cells of the body have access to nutrients and can dispose of waste. This interstitial fluid, whose volume is roughly three times that of all blood in the circulation, is returned to the circulation in the form of lymph, which passes through specialized anatomic structures called *lymph nodes*. The primary lymphoid organs, where lymphocytes are generated, are the bone marrow (B cells, T-cell precursors) and the thymus (T cells). The initiation of an immune response involves the secondary lymphoid organs (lymph nodes, spleen).

The immune system, an interconnected system of vessels, organs, and cells, can be divided into primary and secondary lymphoid organs (see Figure 24-2). *Primary lymphoid organs* are the sites at which **lymphocytes** — the subset of leukocytes that includes B and T cells — are generated and acquire their functional properties. These organs include the thymus, where T cells are generated from

progenitors, and the bone marrow, where B cells are generated. Adaptive immune responses, which require functionally competent lymphocytes, are initiated in *secondary lymphoid organs*, which include lymph nodes and the spleen. All of the cells within lymphoid organs are ultimately derived from hematopoietic stem cells (see Figure 22-18), generated initially in the fetal liver and subsequently in the bone marrow. The total number of lymphocytes in a young man is estimated to be 500×10^9. Roughly 15 percent of these cells are found in the spleen, 40 percent in the other secondary lymphoid organs (tonsils, lymph nodes), 10 percent in the thymus, and 10 percent in the bone marrow; the remainder circulate in the bloodstream or reside in other tissues.

In normal circumstances, the pressure exerted by the pumping heart not only drives transport of the blood within blood vessels, but also forces cell-free liquid across blood vessel walls into the underlying tissue. This liquid delivers both nutrients and proteins, some of which carry out defensive functions. Its volume is up to three times the total blood volume. To maintain homeostasis, the fluid that leaves the circulation must ultimately return, and it does so in the form of *lymph*, via lymphatic vessels. At their most distal ends, lymphatic vessels are open to collect the interstitial fluid that bathes the cells in tissues. The lymphatic vessels merge into larger collecting vessels, which deliver lymph to *lymph nodes* (Figure 24-3). A lymph node consists of a capsule organized into areas that are defined by the cell types that inhabit them. Blood vessels entering a

lymph node deliver B and T cells to it. The lymph that arrives in a lymph node carries soluble antigens and specialized cells that have encountered ("sampled") antigens from the tissue drained by that particular afferent lymphatic vessel. In the lymph node, the cells and molecules required for the adaptive immune response interact, respond to the newly acquired antigenic information, and then execute the necessary steps to rid the body of the pathogen (see Figure 24-3).

FIGURE 24-3 Initiation of the adaptive immune response in lymph nodes. Recognition of antigen by B and T cells (lymphocytes) located in lymph nodes initiates an adaptive immune response. T and B lymphocytes leave the circulation and take up residence in lymph nodes (step 1). Lymph carries antigen in two forms, soluble antigen and antigen-laden dendritic

cells; both are delivered to lymph nodes via afferent lymphatic vessels (steps 2 and 3). Dendritic cells, thus named because of their spine-like projections, are specialized cells of a type termed “antigen-presenting cells”; they degrade antigens into peptides or other small fragments and display them by means of MHC proteins on their surface, thus “presenting” antigens to T cells. Soluble antigen is recognized by B cells (step 4), and antigen-laden dendritic cells present antigen to T cells (step 5). Productive interactions between T and B cells (step 6) allow B cells to move into follicles and differentiate into plasma cells, which produce large amounts of secreted immunoglobulins (antibodies). Efferent lymphatic vessels return lymph from the lymph node to the circulation.

Lymph nodes can be thought of as filters in which antigenic information gathered from distal sites throughout the body is collected and displayed to the immune system in a form suitable to evoke a response. All the relevant steps that lead to activation of a resting lymphocyte take place in lymphoid organs. Cells that have received proper instructions to become functionally active leave the lymph node via efferent lymphatic vessels that ultimately return lymph to the bloodstream. Such activated cells recirculate through the bloodstream and, now ready for action, may reach a location where they again leave the circulation in response to chemotactic cues, move into tissues, and seek out pathogenic invaders, destroy virus-infected cells, or produce the antibodies that recognize and tag the invaders for destruction.

The exit of lymphocytes and other leukocytes from the circulation, the recruitment of these cells to sites of infection, the processing of antigenic information, and the return of immune-system cells to the circulation are all carefully regulated processes that involve specific

cell-adhesion events, chemotactic cues, and the crossing of endothelial barriers, as we will see later in this chapter.

Having introduced the principal types of cells that form the immune system, we return to the first two lines of defense against foreign pathogens: physical barriers and chemical defenses, and an innate immune system.

Mechanical and Chemical Boundaries Form a First Layer of Defense Against Pathogens

As noted already, mechanical and chemical defenses form the first line of host defense against pathogens (see Figure 24-1). Mechanical defenses, which operate continuously, include skin, epithelia, and arthropod exoskeletons, all barriers that can be breached only by mechanical damage or through specific enzymatic attack. Chemical defenses include the low pH found in gastric secretions as well as enzymes such as *lysozyme*, found in tears and in intestinal secretions, that can attack microbes directly.

The essential nature of mechanical defenses is immediately obvious in the case of burn victims. When the integrity of the skin (epidermis and dermis; Figure 1-4) is compromised, the rich source of nutrients in the underlying tissues is exposed, and airborne

bacteria or otherwise harmless commensal bacteria found on the skin can multiply unchecked, ultimately overwhelming the host. Viruses and bacteria have evolved strategies to breach the integrity of these physical barriers. For example, certain pathogenic bacteria (e.g., "flesh-eating bacteria," which are highly pathogenic strains of *Streptococcus*) secrete collagenases that compromise the integrity of connective tissue and so facilitate access of the bacteria to underlying tissue.

Innate Immunity Provides a Second Line of Defense

The innate immune system is activated once the mechanical and chemical defenses have failed and the presence of an invader is sensed (see Figure 24-1). The innate immune system comprises cells and molecules that are always available for immediate response to pathogens. **Phagocytes**, cells that ingest and destroy pathogens (see Figure 17-19), have receptors on their surface that bind to molecules frequently present on pathogens but absent from normal body cells. Many yeasts and other fungi, for instance, have cell walls that contain polymers of the sugar mannose. Such polymers are not found on normal body proteins, and macrophages utilize a *cell surface mannose receptor* to bind many fungal pathogens. Macrophages are widespread throughout tissues and epithelia and can be recruited to sites of infection. Animals that lack an adaptive

immune system, such as insects, rely exclusively on innate defenses to combat infections. Likewise, plants rely exclusively on innate defenses and lack adaptive immunity altogether. Cells of the innate immune system, otherwise resembling lymphocytes, are now categorized as innate lymphoid cells (ILCs) and will be discussed later in this chapter.

Phagocytes and Antigen-Presenting Cells

The innate immune system includes macrophages, neutrophils, and dendritic cells. All of these cells are phagocytic and come equipped with other types of pathogen recognition receptors such as **Toll-like receptors** (**TLRs**; see Figure 24-37 for their molecular structure) and *scavenger receptors* on their cell surface. Like the mannose receptor, these receptors detect broad patterns of pathogen-specific markers, such as bacterial cell-wall constituents or nucleic acids that contain unmethylated CpG or double-stranded RNA, and are thus key sensors for detecting the presence of bacteria or viruses. When these markers bind to TLRs, the cells produce effector molecules, including antimicrobial peptides. Dendritic cells and macrophages whose TLRs have detected pathogens also function as **antigen-presenting cells (APCs)** by processing and displaying foreign materials to antigen-specific T cells, thus bridging the innate and adaptive immune systems. The structure and function of TLRs and their role in activating dendritic cells are described in detail in Section 24.6.

Inflammasomes and Non-TLR Nucleic Acid Sensors

Mammalian cells possess a family of proteins that are capable of recognizing all manner of nonself components and of perceiving danger signals. The molecules recognized by these proteins span a range from components of the bacterial cell wall to uric acid crystals, to heme degradation products, and even to asbestos and silica (Figure 24-4). Once recognized, these danger signals activate the assembly of a multiprotein complex called the **inflammasome**, which activates the effector proteins involved in inflammation. Proteins that make up the inflammasome contain modules that mediate interactions with adapter proteins that ultimately allow a physical connection with and activation of caspase-1, an enzyme that is critical in the production of cytokines that cause inflammation (a process described below). As we will see in Section 24.6, the inflammasome plays an important role in bridging the innate and adaptive immune response.

FIGURE 24-4 The NLRP3 inflammasome. The NLRP3 inflammasome activates caspase-1 only after receiving two signals. Signal 1 is provided by microbial antigens recognized via Toll-like receptors (TLRs) or by binding of endogenous cytokines such as TNF to the TNF receptor (TNFR). Signal 1 causes the up-regulation of NLRP3 (also called *NALP3*) and pro-IL-1β. Signal 2, which activates the NLRP3 inflammasome, can be provided by bacterial pore-forming toxins, by influenza virus M2 protein, by fungal particles via the kinase Syk (as shown for *Candida albicans*), or by cholera toxin. Cytosolic bacterial DNA can also activate the NLRP3 inflammasome, although the molecular details of this mechanism are not yet understood.

The Complement System

Another important component of the innate immune system is the complement system, a collection of serum proteins that can bind

directly to microbial or fungal surfaces. This binding initiates a cascade of protease activation that culminates in, among other things, the formation of a *membrane attack complex*, a multiprotein complex that forms pores in the pathogen's protective membrane (Figure 24-5). The cascade of complement activation is conceptually similar to the blood-clotting cascade, with amplification of the reaction at each successive stage of activation. At least three distinct pathways can activate the complement system. The *classical pathway* requires the presence of antibodies produced in the course of an adaptive immune response and bound to their antigens on the surface of the target microbe. How such antibodies are produced will be described in Section 24.3. This complement pathway represents an example of components of the innate immune system acting in concert with the adaptive immune system.

FIGURE 24-5 Three pathways of complement activation. The classical pathway involves the formation of antibody-antigen complexes. In the mannose-binding lectin pathway, mannose-rich structures found on the surfaces of many pathogens are recognized by mannose-binding lectin. The alternative pathway requires deposition of a special form of the serum protein C3, a major complement component, onto a microbial surface, upstream of which are factors B, D, and P. Each of the activation pathways is a cascade of proteases in which the downstream component is itself a protease. Amplification of activity occurs with each successive step. All three pathways converge on C3, which cleaves C5 and thus triggers formation of the membrane attack complex, leading to destruction of target cells. The small fragments of C3 and C5 generated in the course of complement activation are chemoattractants. They initiate inflammation by attracting neutrophils, phagocytic cells that can kill bacteria at short range or upon ingestion.

In addition to the classical pathway of complement activation, pathogens that contain mannose-rich cell walls activate the complement cascade through the *mannose-binding lectin pathway*. (Note that this is distinct from the macrophage mannose receptor mentioned previously.) Mannose-binding lectin binds to distinctive groups of mannose sugars on the surface of the pathogen, which triggers activation of two mannose-binding lectin–associated proteases, MASP-1 and MASP-2. Protease activation leads to activation of the downstream components of the complement cascade as shown in Figure 24-5. Finally, many microbial surfaces have physical and chemical properties, albeit incompletely understood, that result in activation of complement via the *alternative pathway*, an activation cascade that includes factors B, D, and P, all proteins found in plasma.

The three pathways converge on the activation of complement protein C3. This protein is synthesized as a precursor that contains an internal, strained thioester linkage between a cysteine and a glutamate residue, requiring proteolytic conversion to become fully reactive. C3 is deposited only on antigen-antibody complexes that are nearby. Surfaces that are properly decorated with mannose-binding lectin or that receive C3 deposits via the alternative pathway are similarly targeted. This proximity restriction limits the effects of complement to nearby surfaces, avoiding an inappropriate attack on cells that do not display the targeted antigens.

Regardless of the activation pathway, activated C3 unleashes the terminal components of the complement cascade, complement proteins C5 through C9, culminating in formation of the membrane attack complex, which inserts itself into almost any adjacent biological membrane and renders it permeable by forming a pore. The resulting loss of electrolytes and small solutes leads to lysis and death of the target cell. Whenever complement is activated, the membrane attack complex is formed and results in death of the cell onto which it is deposited. The direct microbe-killing (microbicidal) effect of a fully activated complement cascade is an important mechanism of host defense.

All three complement activation pathways also generate C3a and C5a cleavage fragments, which bind to G protein–coupled receptors and function to attract neutrophils and other cells involved in inflammation. In addition, phagocytic cells, such as **macrophages**, which recognize cells whose surfaces are covalently labeled with fragments from C3, ingest and destroy those cells.

The complement cascade thus fulfills multiple roles in host defense: it can destroy the membranes that envelope a pathogen (bacteria, viruses); it covalently decorates the targeted pathogen so that it may be more readily ingested by phagocytic cells capable of killing the pathogen and presenting its contents to cells that will initiate an adaptive immune response. Finally, the act of complement activation yields signals to attract cells of the innate (neutrophils, macrophages, dendritic cells) and adaptive (lymphocytes) immune

systems to the site of infection. These cues are called *chemotactic signals*.

Natural Killer Cells

In addition to bacterial and eukaryotic parasitic invaders, the innate immune system also defends against viruses. When the presence of a virus-infected cell is detected, still other cell types of the innate immune system become active, seeking out virus-infected target cells and killing them. For instance, when many types of cells (not just immune-system cells) are infected, they synthesize and secrete a class of proteins called *type I interferons* that act as intercellular signals, warning the immune system that an infection is present. The interferons are classified as **cytokines**, small, secreted proteins that help regulate immune responses in a variety of ways. We will encounter other cytokines and discuss some of their receptors as the chapter progresses.

Interferons activate **natural killer (NK) cells**, which belong to the group of *i*nnate *l*ymphoid *c*ells-1 (ILC1). These innate lymphoid cells will be discussed in Section 24.5. Activated NK cells help protect the body in several ways. First, they can kill host cells infected by a virus (hence the name "natural killer"), preventing those infected cells from making additional virus particles that would spread the infection. Second, NK cells secrete type II interferon γ which is essential for orchestrating many other aspects of antiviral defenses

(Figure 24-6). Third, NK cells can kill target cells that have been decorated by antibodies. NK cells recognize their targets by means of several classes of surface receptors capable of yielding stimulatory (promoting cell killing) or inhibitory signals.

FIGURE 24-6 Natural killer cells. Natural killer (NK) cells or ILC1s are an important source of the cytokine interferon γ (IFN-γ), which is involved in antiviral defenses, and can kill virus-infected and cancerous cells directly by means of perforins. These pore-forming proteins allow access to the cytoplasm of the target cell by serine proteases called *granzymes*. Granzymes can also initiate apoptosis through activation of caspases (see Chapter 22). Receptors on NK cells identify infected or stressed cells and stimulate the NK cell to kill them. Other receptors identify normal cells and inhibit NK cell activation.

Inflammation Is a Complex Response to Injury That Encompasses Both Innate and Adaptive Immunity and Helps Destroy Pathogens

When a vascularized tissue (one that is supplied with blood vessels) is injured, the stereotypical response that follows is **inflammation**. The injury may be a consequence of physical or chemical processes, such as torn muscles, a simple paper cut, or infection with a pathogen. Inflammation, also called the *inflammatory response*, is characterized by four classic signs: *redness, swelling, heat*, and *pain*. These signs are caused by increased leakiness of blood vessels (vasodilation), attraction of immune-system cells to the site of damage, and the production of soluble mediators of inflammation, which are responsible for the sensation of heat and pain. Inflammation provides immediate protection through the activation of the cell types and soluble products that together mount the innate immune response and create a local environment conducive to the initiation of the adaptive immune response. If it is not properly controlled, however, inflammation can also be a major cause of tissue damage.

Figure 24-7 depicts the key players in the inflammatory response to bacterial pathogens and the subsequent initiation of an adaptive immune response. Tissue-resident **dendritic cells** sense the

presence of pathogens via their TLRs and respond by releasing small soluble proteins such as cytokines and **chemokines**; the latter act as chemoattractants for immune-system cells. **Neutrophils** leave the circulation and migrate to the site of injury or infection in response to the cytokines and chemokines produced there (see Figure 20-40). Neutrophils, which constitute almost half of all circulating leukocytes, are phagocytic (see Figure 17-19), directly ingesting and destroying pathogenic bacteria and fungi. Neutrophils can interact with a wide variety of pathogen-derived macromolecules via their TLRs. Engagement of these receptors, described in detail below, activates the neutrophils, which produce more cytokines and chemokines. The latter can attract more leukocytes — neutrophils, macrophages, and ultimately lymphocytes (T and B cells) — to the area to fight the infection. Activated neutrophils can also release bacteria-destroying enzymes (e.g., lysozyme and proteases) as well as small peptides with microbicidal activity, collectively called *defensins*. Activated neutrophils also turn on enzymes that generate the superoxide anion radical and other reactive oxygen species (see Section 12.4), which can kill microbes at short range. Neutrophils can also undergo a reaction referred to as *NETosis*. By committing suicide and releasing their nuclear DNA into the extracellular space, neutrophils throw out a fibrous net that can capture microbes and platelets (Figure 24-8). This reaction helps confine invaders to the site where neutrophil activation occurs. Another cell type that contributes to the inflammatory response is the tissue-resident *mast*

cell. When activated by a variety of physical or chemical stimuli, mast cells release histamine, a small molecule that binds to G protein–coupled histamine receptors. This binding leads to increased vascular permeability and thereby facilitates access to the tissue by plasma proteins (e.g., complement) that can act against the invading pathogen.

FIGURE 24-7 Interplay of innate and adaptive immune responses to a bacterial pathogen. Once a bacterium breaches the host's mechanical and

chemical defenses, the bacterium is exposed to components of the complement cascade, as well as to innate immune-system cells that confer immediate protection (step 1). Various inflammatory proteins induced by tissue damage contribute to a localized inflammatory response. Local destruction of the bacterium results in the release of bacterial antigens, which are delivered to the lymph nodes (step 2) via the afferent lymphatic vessels that drain the tissue. Dendritic cells acquire antigen at the site of infection, become migratory, and move to the lymph nodes, where they activate T cells (step 3). In the lymph nodes, antigen-stimulated T cells proliferate and acquire effector functions, including the ability to help B cells (step 4), some of which may move to the bone marrow and complete their differentiation into antibody-secreting plasma cells (step 5). In later stages of the immune response, activated T cells provide additional assistance to antigen-experienced B cells to yield plasma cells that secrete antigen-specific antibodies at a high rate (step 6). Antibodies produced as a consequence of the initial exposure to the bacterium act in synergy with complement to eliminate the infection (step 7), should it persist, or afford rapid protection in the case of re-exposure to the same pathogen.

FIGURE 24-8 In NETosis neutrophils sacrifice themselves to facilitate capture of bacterial pathogens. Upon encounter with bacterial products such as lipopolysaccharides, neutrophils can undergo a form of cell death that results in the release of a network of nuclear DNA and associated molecules (a neutrophil extracellular trap or “NET”). NETs contain antimicrobial components and can kill bacteria extracellularly without reliance on phagocytosis. NETs can physically limit further spread of the pathogens.

A very important early response to infection or injury is the activation of a variety of plasma proteases, including the proteins of the complement cascade discussed above. As we have seen, the cleavage fragments produced during activation of these proteases attract neutrophils to the site of tissue damage (see Figure 24-5). They further induce production of cytokines such as interleukins 1 and 6 (IL-1 and IL-6), which cause inflammation. The recruitment of neutrophils also depends on an increase in vascular permeability, which is controlled in part by lipid-signaling molecules (e.g., prostaglandins and leukotrienes) that are derived from phospholipids and fatty acids. All of these events occur rapidly, starting within minutes of injury. A failure to resolve the cause of this immediate response may result in chronic inflammation with ensuing tissue damage, in which cells of the adaptive immune system play an important role.

When the pathogen burden at the site of tissue damage is high, it may exceed the capacity of innate defense mechanisms to deal with the infection. Moreover, some pathogens have acquired, in the course of evolution, tools to disable or bypass innate immune defenses. In such situations, the adaptive immune response is required to help control the infection. This response depends on specialized cells that are parts of both the adaptive and innate immune systems, including macrophages and dendritic cells, which are capable of ingesting and killing pathogens as well as presenting antigens to the adaptive immune system. Dendritic cells, in particular, can initiate an adaptive immune response by delivering

newly acquired pathogen-derived antigens to secondary lymphoid organs (see Figure 24-7).

Adaptive Immunity, the Third Line of Defense, Exhibits Specificity

Adaptive immunity is the term reserved for the highly specific recognition of foreign substances by antigen-specific receptors, the full elaboration of which requires days or weeks after occurrence of the initial exposure. Lymphocytes bearing antigen-specific receptors are the key cells responsible for adaptive immunity. The B lymphocytes will differentiate into plasma cells that produce a secreted version of their cell surface antigen receptors, proteins called *immunoglobulins* or *antibodies*. Immunoglobulins can neutralize (render inactive) not only bacterial toxins but also harmful agents such as viruses by binding directly to them in a manner that prevents the virus from attaching itself to host cells. The generation of neutralizing antibodies is the rationale underlying virtually all vaccination strategies. Vaccination is a form of active immunization that consists of deliberately exposing an individual to a foreign antigen to elicit protective immunity by generating an adaptive immune response (described below) and antibodies that bind the foreign antigen.

In the same vein, antibodies raised against snake venoms can be administered to the victims of snake bites to protect them from intoxication, provided the administration occurs relatively soon after the bite. The antibodies bind to the toxic proteins in the venom, keeping them from binding to their targets in the host, and in so doing neutralize them. This procedure, called *passive immunization*, can save lives by instant neutralization of a noxious substance such as a toxin. Passive immunization is also used prophylactically to protect those who travel to areas where a disease such as viral hepatitis is endemic; administration of serum from immune individuals provides temporary protection against infection. Antibodies can thus have immediate protective effects. Given that today's medical advances allow the survival of individuals whose immune systems are severely compromised (e.g., cancer patients receiving chemotherapy or radiation, transplant patients with a pharmacologically suppressed immune system, patients who suffer from AIDS, individuals with inborn deficiencies of the immune system), passive immunization can be of immediate practical importance. The deliberate exposure of an animal such as a mouse or rabbit to a foreign substance (*immunization*) allows the production of *antisera* that specifically recognize that substance (the *antigen*). These antisera have become standard components of the cell biologist's toolbox.

KEY CONCEPTS OF SECTION 24.1

Overview of Host Defenses

- Mechanical and chemical defenses provide protection against most pathogens. This protection is immediate and continuous, yet possesses little specificity. Innate and adaptive immunity provide defenses against pathogens that breach the body's mechanical or chemical boundaries (see Figure 24-1).
- The circulatory and lymphatic systems distribute the molecular and cellular players in innate and adaptive immunity throughout the body (see Figure 24-2).
- Innate immunity is mediated by the complement system (see Figure 24-5) and several types of leukocytes, including natural killer cells, neutrophils, and other phagocytic cells, such as macrophages and dendritic cells. The cells and molecules of the innate immune system are deployed rapidly (minutes to hours). Molecular patterns diagnostic of the presence of pathogens can be recognized by Toll-like and other receptors, but the specificity of recognition is modest, as these receptors are capable of recognizing rather broad sets of related molecules.
- Adaptive immunity is mediated by T and B lymphocytes. These cells require days for full activation and deployment, but they can distinguish between closely related antigens. This specificity of antigen recognition is the key distinguishing feature of adaptive immunity.
- Innate and adaptive immunity act in a mutually synergistic fashion. Inflammation, an early response to tissue injury or infection, involves a series of events that combines elements of innate and adaptive immunity (see Figure 24-7).

24.2 Immunoglobulins: Structure and Function

Immunoglobulins (also called *antibodies*), produced by B cells, are the best understood of the molecules that confer adaptive immunity. An individual human has the capacity to make a limitless number of different antibodies, but any given specific antibody is typically made only when the individual has been exposed to the antigen (immunized) to which the antibody will bind specifically; hence antibody production is an adaptive immune response. In this section, we describe the structural organization of immunoglobulins, their diversity, and how they bind to antigens. The mechanisms that generate diverse antibodies are described in Section 24.3.

Immunoglobulins Have a Conserved Structure Consisting of Heavy and Light Chains

Immunoglobulins are abundant serum proteins that fall into several classes with distinct structural and functional properties. Immunoglobulins were identified as the class of serum proteins responsible for antibody activity when they were biochemically purified from serum isolated from immunized animals (called

antiserum). They were purified based on their abilities to mediate the killing of microbes and to bind directly to their corresponding, or *cognate*, antigens. Immunoglobulins of the most common class are composed of two identical *heavy (H) chains*, covalently attached to two identical *light (L) chains* (Figure 24-9; the various classes will be described in the next section). The typical immunoglobulin (sometimes abbreviated *Ig*) therefore has a twofold, symmetric structure, described as H_2L_2. One H_2L_2 antibody molecule can usually bind to two antigen molecules (bivalent binding; see below). An exception to this basic H_2L_2 architecture occurs in the immunoglobulins made by camelids (camels, llamas, vicuñas) and sharks. These animals can make immunoglobulins that are heavy-chain dimers (H_2) and lack light chains.

FIGURE 24-9 The basic structure of an immunoglobulin molecule. Antibodies are serum proteins also known as *immunoglobulins*. They are twofold, symmetric structures composed of two identical heavy chains and two identical light chains. Fragmentation of antibodies with proteases yields

fragments that retain antigen-binding capacity. The protease papain yields monovalent F(ab) fragments, and the protease pepsin yields bivalent $\mathrm{F(ab')_2}$ fragments. The Fc fragment is unable to bind antigen, but this portion of the intact molecule has other functional properties. F(ab) fragments are now commonly made using recombinant DNA technology instead of relying on proteolytic digestion.

A biochemical approach was used to answer the question of how antibodies manage to distinguish among related molecules, that is, how one antibody can bind to its specific antigen but not to another, structurally very similar, molecule. Proteolytic enzymes were used to fragment immunoglobulins, which are rather large proteins (~150 kDa), to identify the regions in the protein that are directly involved in antigen binding (Figure 24-9). The protease papain yields fragments, called *F(ab)* for *a*ntigen *b*inding *f*ragment, that can bind a single antigen molecule (monovalent fragments), whereas the protease pepsin yields bivalent fragments, referred to as $F(ab')_2$ (F = fragment; ab = antibody) that exhibit two binding sites, termed *bivalent binding*. These enzymes are used to convert intact immunoglobulin molecules into monovalent or bivalent reagents. Although F(ab) fragments are incapable of binding two antigens, a property often termed *cross-linking* when applied to antigens displayed at a cell surface, $\mathrm{F(ab')_2}$ fragments can do so. Researchers frequently take advantage of this property to cross-link and thus activate surface receptors. Many receptors, such as the EGF receptor, dimerize upon engagement of ligand (*ligand-induced dimerization*), a prerequisite for full activation of downstream

signaling cascades (see Chapter 16). Many receptors on immune-system cells behave in a similar fashion. The portion released upon papain digestion and incapable of antigen binding is called *Fc* because of its ease of crystallization (F = fragment; c = crystallizable).

Multiple Immunoglobulin Isotypes Exist, Each with Different Functions

Immunoglobulins can be divided into different classes, termed **isotypes**, based on their distinct biochemical properties. There are two light-chain isotypes, κ and λ. The heavy chains show more variation; in mammals, the major heavy-chain isotypes are μ, δ, γ, α and ε. These heavy chains can associate with either κ or λ light chains. Depending on the vertebrate species, further subdivisions occur within the α and γ isotypes, and fish possess an isotype that is not found in mammals. The fully assembled immunoglobulin (Ig) derives its name from the heavy chain: antibodies with μ heavy chains yield IgM; α chains, IgA; γ chains, IgG; δ chains, IgD; and ε chains, IgE. The general structures of the major Ig isotypes are depicted in Figure 24-10. By means of the unique structural features of the Fc portions of their heavy chains, each of the different Ig isotypes carries out specialized functions.

FIGURE 24-10 Immunoglobulin isotypes. The different classes of immunoglobulins, called *isotypes*, may be distinguished biochemically and by immunological techniques. In mice and humans, there are two light-chain isotypes (κ and λ) and five heavy-chain isotypes (μ, δ, γ, ε, α). Each isotype defines a class of immunoglobulin based on the identity of the heavy chain. IgG, IgE, and IgD (not shown) are monomers with generally similar overall structures. IgM and IgA can occur in serum as pentamers and dimers, respectively, accompanied by an accessory subunit, the J chain, in covalent disulfide linkage. This volume-rendered depiction of the immunoglobulins highlights their modular design, with each barrel representing an individual Ig domain. Different isotypes have different functions. See Figure 24-13 for definitions of abbreviations.

The IgM molecule is secreted as a pentamer of H_2L_2 chains, stabilized by disulfide bonds between the ends of the heavy chains and an additional chain, the J chain. In its pentameric form, IgM possesses 10 identical antigen-binding sites (2 for each H_2L_2), which allow high-avidity interactions with surfaces that display the cognate antigen. *Avidity* is defined as the product of the *strength* of interactions (affinity) of the available individual binding sites and the *number* of such binding sites. Combining many low-affinity

interactions can lead to a high-avidity interaction (as in Velcro). Upon its deposition on a surface that carries the cognate antigen, the pentameric IgM molecule assumes a conformation that is highly conducive to activation of the complement cascade; it thus is an effective means of damaging the membrane onto which it is adsorbed and onto which complement proteins are deposited as a consequence.

The IgA molecule also interacts with the J chain, forming a dimer of H_2L_2 molecules. Dimeric IgA can bind to an IgA receptor found on the basolateral plasma membrane of epithelial cells, where its binding triggers receptor-mediated endocytosis. Subsequently, the IgA receptor is cleaved, and the dimeric IgA, with a fragment of the receptor (the so-called "secretory piece") still attached, is released from the apical side of the epithelial cell. This process, called **transcytosis**, is an effective means of delivering immunoglobulins from the basolateral side of an epithelium to the apical side (Figure 24-11a). Tears and other secretions, especially in the gastrointestinal tract, are rich in IgA — grams of immunoglobulin are secreted from the blood into the lumen of the GI tract each day! — and so provide protection against environmental pathogens.

FIGURE 24-11 Transcytosis of IgA and IgG. (a) IgA, found in tears and in the secretions of various mucous membranes, must be transported across the epithelium. IgA binds to the polymeric IgA receptor on the basolateral surface of an epithelial cell and is endocytosed. As the resulting complex is transported across the epithelial monolayer, a portion of the receptor is cleaved, and the

IgA, still bound to a portion of the receptor, the secretory piece, is released at the apical side. (b) Suckling rodents acquire Ig from their mother's milk. At the apical surface of its intestinal epithelial cells, the newborn possesses the neonatal Fc receptor (FcRn), whose structure resembles that of class I MHC molecules (see Figure 24-24). After this receptor binds to the Fc portion of IgG, transcytosis moves the acquired IgG to the basolateral side of the epithelium. In humans, the syncytial trophoblast in the placenta expresses FcRn and so mediates acquisition of IgG from the maternal circulation and its delivery to the fetus (transplacental transport).

The IgG isotype is important for neutralization of virus particles. This isotype also helps prepare particulate antigens, such as viruses or larger fragments of bacteria, for acquisition by cells equipped with receptors specific for the Fc portion of the IgG molecule (see below).

The immune system of the newborn mammal is immature, but protective antibodies are transferred from the mother to the newborn via the mother's milk. The receptor responsible for capturing maternal IgG is the neonatal Fc receptor (FcRn), which in rodents is present on intestinal epithelial cells. Maternal IgG captured by an FcRn on the luminal side of the newborn's intestinal tract is transcytosed across the gut epithelium and released into the infant's circulation, generating passive immune protection of the infant rodent (Figure 24-11b). In humans, FcRn is found on fetal cells that contact the maternal circulation in the placenta. Transcytosis of IgG antibodies from the maternal circulation across the placenta delivers maternal antibodies to the fetus. These

maternal antibodies will protect the newborn until its immune system is sufficiently mature to produce antibodies on its own. In adults, FcRn is also expressed on endothelial cells and helps control the turnover of IgG in the circulation as well as the delivery of IgG across the endothelial barrier and into underlying tissue.

As we will see in Section 24.3, the IgM and IgD isotypes are expressed as membrane-bound receptors on newly generated B cells. Here the μ chains have an important role in B-cell development and activation.

Each Naive B Cell Produces a Unique Immunoglobulin

The *clonal selection theory* stipulates that each *naive* B lymphocyte (not yet having seen its specific antigen) expresses on its plasma membrane an antigen-binding receptor of unique specificity. The receptor is an antibody extended at its C-terminus by a hydrophobic sequence that anchors the protein in the plasma membrane, as we discuss later (see Figure 24-19). When a lymphocyte encounters the antigen for which it is specific, clonal expansion occurs. This allows an amplification of the response, culminating in production and secretion by plasma cells of large amounts of this specific antibody (the same one made by the original precursor cell) (Figure 24-12). (Note that clonal expansion is rapid cell division of this single cell to

form a group of cells — a clone — that all originate from this precursor cell.) The antigen-specific antibody is responsible for binding to the antigen and subsequently mediating the clearing of the antigen out of the body. In a typical immune response, the antigen that elicits the response is of complex composition: even the simplest virus contains several distinct proteins, and each protein may present to the immune system several molecularly distinct features that can be recognized independently of one another. Thus many individual lymphocytes respond to different parts of a given antigen and expand into independent clones in response to it, each producing its own antigen-specific receptor and antibody of unique structure and therefore with unique binding characteristics (affinity). Because each lymphocyte is endowed with a unique receptor and clonally expands in response to antigen, this response of multiple, independent B cell precursors is characterized as *polyclonal*.

FIGURE 24-12 Clonal selection. The clonal selection theory proposes the existence of a large set of B lymphocytes, each expressing on its surface a unique antigen-specific receptor (indicated by different colors). The receptor is an antibody extended at its C-terminus by a hydrophobic sequence that anchors it in the plasma membrane (see Figure 24-19). The antigen that fits with the receptor carried by a particular lymphocyte binds to it and stimulates that lymphocyte to expand clonally. From a modest number of antigen-specific cells, a large number of cells of the desired specificity may be generated. Many of these cells will differentiate into plasma cells, where a form of the antigen-specific receptor lacking the membrane anchor is secreted as an antibody. Note that, like secreted antibodies, the cell surface antigen-specific receptors each have two H and two L chains.

B-cell tumors, which represent malignant clonal expansions of individual B-lymphocytes, enabled the first molecular analysis of the processes that underlie the generation of antibody diversity. A key observation was that tumors derived from lymphocytes may produce large quantities of a single type of secreted immunoglobulin. Some of the light chains of these immunoglobulins are secreted in the urine of patients with such tumors. These light chains, called *Bence-Jones proteins* after their discoverers, can be readily purified and afforded the first target for a protein chemical analysis of immunoglobulins.

Two key observations emerged from this work. First, no two independent B-cell tumors produced light chains with identical biochemical properties, suggesting that they were all unique in sequence. Second, the differences in amino acid sequence that distinguished one light chain from another were not randomly distributed but were clustered in a domain referred to as the *variable region of the light chain*, or V_L. This domain comprises the N-terminal ~110 amino acids of the light chain. The remainder of the sequence is identical for the different light chains (provided they derive from the same isotype, either κ or λ) and is therefore referred to as the *constant region*, or C_L. Immunoglobulins unique to each individual patient were subsequently purified from the patients' serum. Sequencing of the heavy chains from these preparations showed that the variable residues that distinguished one heavy chain from

another were again concentrated in a well-demarcated domain, referred to as the *variable region of the heavy chain*, or V_H.

An alignment of variable-region sequences obtained from different light chains showed a nonrandom pattern of regions of variability, revealing three *hypervariable regions* — HV1, HV2, and HV3 — that are sandwiched between what are called *framework regions* (Figure 24-13a). (Similar alignments for the immunoglobulin heavy-chain sequences also yielded hypervariable regions.) In the properly folded three-dimensional structure of immunoglobulins, these hypervariable regions are in close proximity (Figures 24-13b and 24-14) and make contact with antigen. Thus that portion of an Ig molecule containing the hypervariable regions constitutes the antigen-binding site. For this reason, hypervariable regions are also referred to as *complementarity-determining regions (CDRs)*.

FIGURE 24-13 Hypervariable regions and the immunoglobulin fold. (a) Amino acid variability varies with residue position in Ig light chains. Here the percentage of variable-region sequences with variant amino acids is plotted for each position in the sequence. Positions for which many different amino acid side chains are present are assigned a high variability index; those that are invariant among the sequences compared are assigned a value of 0. This analysis reveals three regions of increased variability: hypervariability (HV) regions 1, 2, and 3; these regions are also called *complementarity-determining*

regions (CDRs) because the surface topology these regions create are complementary to the surface of the antigen to which the immunoglobulin binds. (b) Volume-rendered depiction of $F(ab')_2$ fragment (*right*) and ribbon diagram of a typical Ig light-chain variable region (V_L) with the positions of the hypervariable regions indicated in red (*left*). The hypervariable regions are found in the loops that connect the β strands and make contact with antigen. The β strands (rendered as arrows) make up two β sheets and constitute the framework region, which has a similar fold in all antibody domains. Each variable and constant domain has this characteristic three-dimensional structure, called the *immunoglobulin fold*. L = light chain; H = heavy chain; $V_H = \text{heavy-chain}$ variable region; $V_L = \text{light-chain}$ variable region; $C_H1, C_H2, C_H3 = \text{heavy-chain}$ constant domains; $C_L = \text{light-chain}$ constant region.

FIGURE 24-14 Immunoglobulin structure. This model shows the three-dimensional structure of an immunoglobulin molecule complexed with hen egg-white lysozyme (a protein antigen) as determined by x-ray crystallography.

[Data from E. A. Padlan et al., 1989, *Proc. Nat'l Acad. Sci. USA* **86**:5938, PDB ID 1igt, 3hfm.]

The difficulty of encoding directly in the inherited genome (germ line) all the information necessary to generate the enormously diverse antibody repertoire (more than a million different antibody molecules in what we now know is a genome encoding about 20,000 independent genes) led to suggestions of unique genetic mechanisms to account for this diversity. Given the size of a typical antibody heavy chain and light chain (each heavy chain–light chain combination, if encoded as such, would require 2.5–3.5 kb of DNA, depending on the isotype), it is immediately obvious that encoding a set of antibody molecules of sufficient diversity to provide adequate protection against the wide array of pathogens and other foreign substances to which an organism is exposed would rapidly exhaust its DNA-coding capacity. We shall see that, indeed, unique mechanisms are at work to create an adequately diverse set of antibodies.

Immunoglobulin Domains Have a Characteristic Fold Composed of Two β Sheets Stabilized by a Disulfide Bond

Both the variable and constant domains of immunoglobulins fold into a compact, three-dimensional structure, an immunoglobulin (Ig) domain, composed exclusively of β sheets (see Figure 24-13b). A typical Ig domain contains two β sheets (one with three strands and one with four strands) held together like a sandwich by a disulfide

bond. The residues that point inward are mostly hydrophobic and help stabilize this sandwich structure. The residues exposed to the aqueous environment show a greater frequency of polar and charged side chains. The spacing of the cysteine residues that make up the disulfide bond and a small number of strongly conserved residues characterize this evolutionarily ancient structural motif, termed the **immunoglobulin fold**. The basic immunoglobulin fold is also found in numerous eukaryotic proteins that are not directly involved in antigen-specific recognition, including the Ig superfamily of cell-adhesion molecules, or Ig CAMs (see Chapter 20).

The region on an antigen that makes contact with the corresponding antibody is called an **epitope**; the portion of the immunoglobulin that makes contact with antigen is the **paratope**. A protein antigen usually contains multiple epitopes, which are often exposed loops or surfaces on the protein and are thus able to bind to different antibody molecules. Each homogeneous antibody preparation derived from a clonal population of B cells recognizes a single molecularly defined epitope on the corresponding antigen.

To determine the structure of an antibody complexed to its cognate epitope on an antigen, it is important to have a source of homogeneous immunoglobulin and of antigen in pure form (see Chapter 3). As we have seen, homogeneous immunoglobulins can be obtained from B-cell tumors, but in that case, the antigen for which the antibody is specific is usually not known. The breakthrough for

generating homogeneous antibody preparations suitable for structural analysis was the development of techniques to obtain antibodies from hybridomas by use of a special selection medium. The creation of immortalized cell lines that produce antibodies of defined specificity, called **monoclonal antibodies**, has yielded essential tools for the cell biologist. Monoclonal antibodies are widely used not only for the specific detection of macromolecules, but also for detection and quantitation of drugs, drug metabolites, and even signaling molecules such as cAMP. Monoclonal antibodies can detect proteins and their modifications (e.g., phosphorylation, nitrosylation, methylation, acetylation, etc.) as well as complex carbohydrates, (glyco)lipids, and nucleic acids and their modifications. They have therefore found widespread use in the laboratory as well as for diagnostic and therapeutic purposes.

We now have detailed insights into the structure of a large number of monoclonal antibodies, each in a complex with its specific antigen. There are no hard-and-fast rules that describe these interactions, other than the usual rules of molecular complementarity of proteins with other molecules and macromolecules (see Chapter 3). The CDRs make the most important contributions to the antigen-antibody interface. The CDR3 of the V_H region of the Ig heavy chain plays a particularly prominent role, as does the CDR3 of the V_L region of the Ig light chain.

An Immunoglobulin's Constant Region Determines Its Functional Properties

As we have seen, antibodies recognize antigen via their variable regions. Their constant regions determine which effector molecules they recruit to neutralize the pathogen.

Antibodies attached to a viral or microbial surface can be recognized directly by cells that express receptors specific for the Fc portion of immunoglobulins. These **Fc receptors (FcRs)**, which are specific for individual classes and subclasses of immunoglobulins, display considerable structural and functional heterogeneity. By means of FcR-dependent events, specialized phagocytic cells such as dendritic cells and macrophages can bind to antibody-decorated particles or cells and then ingest and destroy them. The decoration of an antigenic target with bound antibodies, or its covalent modification with complement components, is called **opsonization**. FcR-dependent events also allow some immune-system cells (e.g., monocytes and natural killer cells) to directly engage target cells that display viral or other antigens to which antibodies are attached. This engagement may induce the immune-system cells to release toxic small molecules (e.g., reactive oxygen species) or the contents of cytotoxic granules, including perforins and granzymes. *Perforins* are proteins that can attach themselves to the surface of the engaged target cell and form pores in its membrane. These newly formed pores allow access by *granzymes*, proteases that initiate a sequence

of events that will ultimately kill the target cell (see Figure 24-6). This process, called *antibody-dependent cell-mediated cytotoxicity (ADCC)*, illustrates how cells of the innate immune system interact with, and benefit from, the products of the adaptive immune response.

Antigen-antibody (immune) complexes of some immunoglobulin isotypes can initiate the classical pathway of complement activation (see Figure 24-5). IgM and IgG3 are particularly good at complement activation, but all IgG classes can in principle activate complement, whereas IgA and IgE are unable to do so. The large amounts of IgA found in the gut contribute to its barrier function by neutralizing gut-resident microbes.

KEY CONCEPTS OF SECTION 24.2

Immunoglobulins: Structure and Function

- Most immunoglobulins (antibodies) are composed of two identical heavy (H) chains and two identical light (L) chains (H_2L_2). Each chain contains a variable (V) region and a constant (C) region. Proteolytic fragmentation yields monovalent F(ab) and bivalent $F(ab')_2$ fragments, which contain variable-region domains that retain antigen-binding capability (see Figure 24-9). The Fc fragment contains constant-region domains and determines their ability to activate complement components or bind to receptors specific for Fc regions expressed on leukocytes.
- Immunoglobulins are divided into classes based on the constant regions of their heavy chains (see Figure 24-10). In mammals, there are five major classes: IgM, IgD, IgG, IgA, and IgE; the corresponding heavy chains are referred to as *μ, δ, γ, α* and *ε*. There are two major classes of light chains, κ and λ, again characterized by the attributes of their constant regions.

- IgM and IgA can form higher order structures: IgM forms pentamers (five identical H_2L_2 copies); and IgA forms dimers (two identical H_2L_2 copies).
- Each individual B lymphocyte expresses an immunoglobulin of unique sequence and is therefore uniquely specific for a particular antigen. Upon recognition of antigen, only a B lymphocyte that bears a receptor specific for it will be activated and expand clonally (clonal selection) (see Figure 24-12).
- The antigen specificity of antibodies is conferred by their variable regions, which contain regions of high sequence variability, called *hypervariable* or *complementarity-determining regions* (see Figure 24-13a). These hypervariable regions are positioned at the tip of the variable region, where they can make specific contacts with the antigen for which a particular antibody is specific.
- The repeating immunoglobulin domains that make up immunoglobulin molecules have a characteristic three-dimensional structure, the immunoglobulin fold, which consists of two β sheets held together in a sandwich by a disulfide bond (see Figure 24-13b).
- The constant regions of the heavy chains endow antibodies with unique effector functions, such as the capacity to bind complement, the ability to be transported across epithelia, or the ability to interact with receptors specific for the Fc portion of immunoglobulins.

24.3 Generation of Antibody Diversity and B-Cell Development

Pathogens have short replication times, are quite diverse in their genetic makeup, and evolve quickly by mutation, generating enormous antigenic variation. An adequate defense must therefore be capable of mounting an equally diverse response. Antibodies provide the diversity required for successful host defense. The timing of the antibody response and its necessary adjustment to changes in the antigenic makeup of the pathogen pose unique demands on the organization and regulation of the adaptive immune system. A unique mechanism has evolved that allows not only virtually limitless variation in the set of antibodies that can be produced (called the *repertoire*), but also rapid improvement in the binding affinity of those antibodies to meet the demands posed by an ongoing viral or bacterial infection. Because optimal antibody production by B cells requires assistance from T cells, we will see below that the molecular mechanisms underlying lymphocyte diversity are fundamentally similar for B and T cells.

B cells, which are responsible for antibody production, make use of a unique mechanism by which the genetic information required for synthesis of immunoglobulin heavy and light chains is stitched together from separate DNA sequences, or Ig gene segments, to create a functional transcription unit. The recombination mechanism that combines Ig gene segments itself dramatically

expands the variability in sequence precisely at those sites where these genetic elements are joined together. This mechanism for generating a diverse array of antibodies is fundamentally different from meiotic recombination, which occurs only in germ cells, and from alternative splicing of exons (see Chapter 7). Because this recombination mechanism occurs in somatic cells but not in germ cells, it is known as *somatic gene rearrangement* or *somatic recombination*. This unusual recombination mechanism, unique to antigen-specific receptors on B and T lymphocytes, makes it possible to specify an enormously diverse set of receptors with minimal expenditure of DNA coding space. The discovery of somatic recombination is detailed in Classic Experiment 24.1.

The ability to combine discrete genetic elements at will (combinatorial diversity), in addition to the generation of yet more sequence diversity in the encoded receptors by the underlying recombination mechanisms themselves, allows adaptive immune responses against a virtually limitless array of antigens, including molecules encoded by the host and chemical structures not naturally found in nature. Thus there are mechanisms at work not only to create this enormous diversity, but also to impose tolerance to curtail unwanted reactivity against self components. Neither mechanism is perfect: the adaptive immune system cannot generate receptors for all foreign substances. Furthermore, the unavoidable price we pay for how we generate B- and T-cell receptors is the

likelihood of self-reactive receptors, which are implicated in **autoimmunity**.

A Functional Light-Chain Gene Requires Assembly of V and J Gene Segments

Genes encoding intact immunoglobulins do not exist already assembled in the genome, ready for expression. Instead, the required gene segments are brought together and assembled in the course of B-cell development. The organization of the region of the genome containing the immunoglobulin genes is shown in Figure 24-15. In B cells, the DNA in this region is rearranged to generate assembled and fully functional immunoglobulin-encoding genes in each B cell and its descendants. Although in the course of B-cell development the rearrangement of heavy-chain genes occurs before the rearrangement of light-chain genes, we discuss light-chain genes first, because of their less complex organization.

FIGURE 24-15 Overview of somatic gene rearrangement in immunoglobulin DNA. The stem cells that give rise to B cells contain multiple gene segments encoding portions of immunoglobulin heavy and light chains. During development of a B cell, somatic recombination of these gene segments yields functional light-chain genes (a) and heavy-chain genes (b). Each V gene segment carries its own promoter. Rearrangement brings an enhancer linked to or contained within the immunoglobulin locus close enough to the combined sequence to activate transcription. The light-chain variable region (V_L) is encoded by two joined gene segments, and the heavy-chain variable region (V_H) is encoded by three joined segments. Note that the chromosomal regions encoding immunoglobulins contain many more V, D, and J segments than those shown. In addition, the κ light-chain locus contains a single constant (C) segment, as shown, but the heavy-chain locus contains several distinct C segments (not shown) that encode the different immunoglobulin isotypes, as we detail later.

The immunoglobulin light-chain genes consist of clusters of V gene segments, followed downstream by a single C segment. Each V gene

segment carries its own promoter sequence and encodes the bulk of the light-chain variable region, although a small piece of the nucleotide sequence encoding the light-chain variable region is missing from the V gene segment. This missing portion is provided by one of the multiple J segments located between the V segments and the single C segment in the unrearranged (or germ-line) κ light-chain locus (Figure 24-15a). (This J segment is a genetic element, not to be confused with the J chain, a polypeptide subunit of the pentameric IgM molecule and found also in association with IgA; see Figure 24-10.) In the course of B-cell development, commitment of a B-cell precursor to use a particular V gene segment — a random process — results in its physical juxtaposition with one of the J segments, again a random choice, to form an exon (V_L) encoding the entire light-chain variable region (Figure 24-15a). This DNA rearrangement not only generates an intact and functional light-chain gene, but also places the promoter sequence of the rearranged gene within controlling distance of enhancer elements, located near the light-chain constant-region exon, that are required for its transcription. Only a fully rearranged light-chain gene is transcribed and subsequently translated into protein.

Recombination Signal Sequences

Detailed DNA sequence analysis of the light-chain and heavy-chain regions revealed a conserved sequence element at the 3′ end of each V gene segment. This conserved element, called a *recombination*

signal sequence (RSS), is composed of heptamer and nonamer sequences separated by a 23-bp spacer. At the 5′ end of each J segment, there is a similarly conserved RSS that contains a 12-bp spacer (Figure 24-16). The 12- and 23-bp spacers separate the conserved heptamer and nonamer sequences by one and two turns of the DNA helix, respectively.

FIGURE 24-16 DNA elements involved in V(D)J recombination in the immunoglobulin loci. Schematic representation of the immunoglobulin light-chain (*top*) and heavy-chain locus (*bottom*). At its 3′ end, each immunoglobulin V region coding sequence abuts a recombination signal, composed of a conserved heptamer (7 bp) and a conserved nonamer (9 bp) sequence, separated by a 12-bp spacer of variable sequence. The combination of heptamer, nonamer, and spacer is called a *recombination signal sequence (RSS)*. Recombination requires juxtaposition of the gene segment that recombines with a second gene segment with an RSS, which carries a heptamer and nonamer sequence that is complementary and antiparallel to the first RSS. For the second RSS, the spacer is 23-bp long, and of variable sequence. For the light-chain locus, the RSSs that flank the V and J segments are separated by intervening DNA. Recombination can occur only between elements that carry RSSs of different spacer length (the “12-23” rule). The heavy-chain locus comprises three sequence elements that can rearrange. The V region of the heavy chain carries an RSS at its 3′ end, the D segments are flanked on their 5′ and 3′ ends by an RSS, and the J segments carry an RSS at their 5′ end. The organization of the immunoglobulin heavy-

chain locus thus enables rearrangements of D to J, and of V to DJ, but direct rearrangements of V to J are not allowed, as this would violate the 12-23 rule.

Somatic recombination is catalyzed by two enzymes, the RAG1 and RAG2 recombinases, which are expressed only in lymphocytes. Thus these rearrangements do not occur in any other cells of the body. Juxtaposition of the two gene segments to be joined is stabilized by the RAG1/RAG2 complex (Figure 24-17). The structure of the RAG1/RAG2 complex juxtaposes the RSSs so that proper covalent joining of the immunoglobulin gene segments can occur, with concomitant release of the intervening DNA, which is released as a covalently closed, circular DNA molecule.

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

FIGURE 24-17 RAG1/RAG2 structure. The RAG1 and RAG2 proteins (light and dark purple) are responsible for bringing together the immunoglobulin gene segments for rearrangement. RAG1/RAG2 complexes with the recombination signal sequences, positioning the 12- and 23-bp spacer sequences to enable cleavage at the boundary of the coding sequence and the heptamer of the RSS.

[Data from M.-S. Kim et al., 2015, *Nature* **518**:507–511, PDB ID 4wwx; and F. F. Yin et al., 2009, *Nat. Struct. Mol. Biol.* **16**:499–508, PDB ID 3gna.]

Defects in the synthesis of RAG proteins obliterate the possibility of somatic gene rearrangements. As described below, the rearrangement process is essential for B-cell development; consequently, RAG deficiency leads to the complete absence of B cells. People with defects in RAG gene function suffer from severe immunodeficiency. Targeted deletion of RAG genes in mice likewise leads to a complete defect in immunoglobulin (and T-cell receptor) gene rearrangement, resulting in a developmental block in the generation of B and T lymphocytes. ■

Junctional Imprecision

In addition to the random selection of V and J gene segments, processing of the intermediates created in the course of somatic recombination provides an additional means for expanding the variability of immunoglobulin sequences. This additional variability is created at the junction of the segments to be joined by random insertion or deletion of nucleotides to one of the cut ends before the V and J segments are joined, a process termed *junctional imprecision*. Whenever a V and a J segment recombine, the sequence and reading frame of the VJ product cannot be predicted; only one in three recombination reactions results in a reading frame that is compatible with light-chain synthesis.

Light-chain diversity therefore arises not only from the combinatorial use of V and J gene segments, but also from

junctional imprecision. Inspection of the three-dimensional structure of the light chain shows that the highly diverse joint generated as a consequence of junctional imprecision forms part of a loop — hypervariable region 3 (HV3) — that projects into the antigen-binding site and makes contact with antigen (see Figure 24-13b).

Rearrangement of the Heavy-Chain Locus Involves V, D, and J Gene Segments

The organization of the heavy-chain locus is more complex than that of the κ light-chain locus. The heavy-chain locus contains not only a large tandem array of V segments (each equipped with its own promoter) and multiple J segments, but also multiple D (diversity) segments (see Figure 24-15b). Somatic recombination of a V, a D, and a J segment generates a rearranged sequence encoding the heavy-chain variable region (V_H).

At the 3′ end of each V segment in heavy-chain DNA, there are conserved heptamer and nonamer sequences separated by spacer DNA, similar to the RSSs in light-chain DNA. These RSSs are also found in complementary and antiparallel configuration at the 5′ end and the 3′ end of each D segment (Figure 24-16). The J segments are similarly equipped at their 5′ end with the requisite RSS. The spacer

lengths in these RSSs are such that D segments can join to J segments, and V segments to already rearranged DJ segments. However, neither direct V-to-J nor D-to-D joining is allowed, in compliance with the 12-23-bp spacer rule. Heavy-chain rearrangements proceed via the same mechanisms described above for light-chain rearrangements.

In the course of B-cell development, the heavy-chain locus is always rearranged first, starting with D-J rearrangement. D-J rearrangement is followed by V-D-J rearrangement. In the course of the D-J and V-D-J rearrangements, an enzyme called *terminal deoxynucleotidyl transferase (TdT)* may add nucleotides to free 3′ OH ends of DNA in a template-independent fashion. Up to a dozen or so nucleotides, called the *N-region* or *N-nucleotides*, may be added, generating additional sequence diversity at the junctions whenever D-J and V-D-J rearrangements occur (Figure 24-18, step **7**). As with rearrangements forming the light-chain gene, only one in three rearrangements yields the proper reading frame for the rearranged VDJ sequence. If the rearrangement yields a sequence encoding a functional protein, it is called *productive*. Although the heavy-chain locus is present on each of two homologous chromosomes, only one productive rearrangement is permitted, as we will see below.

FIGURE 24-18 The sequential steps in V(D)J recombination. Step 1: Linear depiction of the immunoglobulin gene segments to be recombined. Each immunoglobulin gene segment carries a recombination signal sequence. For the V regions, at their $3'$ end, for the J segments (light chain) at their $5'$ end and for a rearranged DJ segment (heavy chain) also at the $5'$ end. Step 2: The RAG1/RAG2 recombinase makes a single strand cut to generate a free $3'$ OH hydroxyl group. Step 3: The $3'$ OH group attacks the bottom strand to create a covalently closed hairpin. The intervening DNA, with an RSS at either end, is excised precisely at the boundaries of the RSS and yields a covalently closed "excision circle" (circularization step not shown in the figure). The gene segments that participate in rearrangement are held in close proximity by the RAG1/RAG2 recombinase and associated proteins. Step 4: The covalently closed hairpins at the end of the coding sequences can be opened either symmetrically (*left*) or (step 5) asymmetrically (*right*). If the hairpin is opened asymmetrically (*left*), the unpaired nucleotides may be removed by nucleases to produce a "flush" end (not shown) or result in a short palindromic sequence that can be rendered flush by "filling in" the missing nucleotides (step 7); this adds nucleotides to where the actual junction will occur, thus creating additional variability in the final product of rearrangement. These nucleotides are called *P nucleotides* because of their palindromic

nature. Even if the hairpin opens symmetrically (step 4, *right*), the enzyme terminal deoxynucleotidyl transferase (TdT) can add random nucleotides to the free 3′ OH in a template-independent manner (step 6), thus increasing sequence diversity at the joint. The target of TdT activity is confined to V, D, and J elements of the immunoglobulin heavy-chain locus. Once the ends of the coding sequences have been rendered flush (step 7), the coding ends are ligated together by nonhomologous end joining.

An enhancer located downstream of the cluster of J segments and upstream of the constant-region segment activates transcription from the promoter at the 5′ end of the rearranged VDJ sequence (see Figure 24-15). Splicing of the primary transcript produced from the rearranged heavy-chain gene generates a functional mRNA encoding the μ heavy chain. For both heavy-chain and light-chain genes, somatic recombination places the promoters upstream of the V segments within functional reach of the enhancers necessary to allow transcription, so that only rearranged VJ and VDJ sequences, and not the V segments that remain in the germ-line configuration, are transcribed.

Somatic Hypermutation Allows the Generation and Selection of Antibodies with Improved Affinities

In addition to somatic recombination and junctional imprecision, antigen-activated B cells can undergo an additional diversity-generating process called *somatic hypermutation*. Upon exposure to

antigen and receipt of the proper signals, most of which are provided by T cells, expression of activation-induced deaminase (AID) is turned on. This enzyme deaminates cytosine residues, converting them to uracil. When a B cell that carries this lesion replicates its DNA, it may place an adenine on the complementary strand, thus generating a G-to-A transition (see Figure 5-14). Alternatively, the uracil may be excised by DNA glycosylase to yield an abasic site. Such abasic sites, when copied, give rise to an A, G, or C in the complementary DNA strand. That is, a C:G base pair can be replaced by somatic hypermutation with a T:A, A:T, or G:C base pair. Mutations thus accumulate with every successive round of B-cell division, yielding numerous mutations in the rearranged VJ and VDJ segments. Error-prone filling by DNA polymerase of gaps created by nucleotide excision repair also contributes to somatic hypermutation.

The process of somatic hypermutation occurs when lymphocytes reside in specialized microanatomic structures known as *germinal centers*. These structures, which arise within the follicles of secondary lymphoid organs upon immunization, consist of foci of thousands of rapidly proliferating and hypermutating B cells. In addition to B cells, germinal centers contain follicular dendritic cells, a cell type that serves as a depot for antigen that can be retrieved by B cells, and a small number of helper T cells specialized in providing selective signals that control B cells. Many of the somatic mutations induced by AID are deleterious, in that they

reduce the affinity of the encoded antibody for an antigen, but some improve the encoded antibody's affinity for an antigen. In a process analogous to Darwinian evolution, B cells carrying surface immunoglobulins with affinity-increasing mutations have a selective advantage in picking up antigen from follicular dendritic cells, which allows them to successfully compete for signals from the limiting number of helper T cells residing in the germinal center (described in some detail in Section 24.6). These signals trigger the proliferation, and thus the clonal selection, of B cells that have on their surface antibodies with higher affinity for the target antigen. This triggers further proliferation and additional mutations and differentiation into antibody-secreting plasma cells or memory B cells. The net result is the generation of a B-cell population whose antibodies, as a rule, show a higher affinity for the antigen.

In the course of an immune response, or upon repeated immunization, the adaptive immune response therefore exhibits *affinity maturation* — an increase in the average affinity of antibodies for an antigen as a function of time after antigen exposure — as the result of somatic hypermutation and selection. Antibodies produced following this phase of the adaptive immune response display affinities for antigen in the nanomolar (or better) range. For reasons that are not fully understood, but likely related to the chromatin structure of the rearranged immunoglobulin loci, the activity of AID is focused mainly on rearranged VJ and VDJ segments, and this targeting may therefore require active transcription. The entire

process of somatic hypermutation is strictly antigen-dependent and shows an absolute requirement for interactions between the B cells and certain T-cell types.

B-Cell Development Requires Input from a Pre-B-Cell Receptor

B cells destined to make immunoglobulins must rearrange the necessary gene segments to assemble functional heavy-chain and light-chain genes. These rearrangements occur in a carefully ordered sequence during the development of a B cell, starting with heavy-chain rearrangements. Moreover, as noted above, the rearranged heavy-chain contains, near its C-terminus, a membrane-spanning segment that traverses the plasma membrane (Figure 24-19; also see Figure 24-20). This membrane-bound receptor first executes a cell-fate decision necessary to drive further B-cell development (and antibody synthesis) by permitting subsequent rearrangement of the light-chain genes. Only a productive rearrangement that yields an in-frame VDJ combination can generate a complete μ heavy chain. The production of that μ chain serves as a signal to the B cell that it has successfully accomplished rearrangement and that no further rearrangements of the heavy-chain locus on the remaining gene copy are required. Recall that each lymphocyte precursor starts out with two immunoglobulin locus–bearing, homologous chromosomes in the germ-line

(unrearranged) configuration. In accordance with clonal selection theory, which stipulates that each lymphocyte ought to come equipped with a single antigen-specific receptor, continued rearrangement would entail the risk of producing B cells with two different heavy chains, each with different specificity — an undesirable outcome.

FIGURE 24-19 Structure of the pre-B-cell receptor and its role in B-cell development. Successful rearrangement of V, D, and J heavy-chain gene segments allows synthesis of membrane-bound μ heavy chains in the endoplasmic reticulum (ER) of a pre-B cell. At this stage, no light-chain gene rearrangement has occurred. Newly made μ chains assemble with surrogate light chains, composed of λ5 and VpreB, and Igα/Igβ to yield the pre-B-cell receptor, pre-BCR (step 1). This receptor drives proliferation of those B cells that carry it. It

also suppresses rearrangement of the heavy-chain locus on the other chromosome and so mediates allelic exclusion. In the course of proliferation, the synthesis of λ5 and VpreB is shut off (step 2), resulting in "dilution" of the available surrogate light chains and reduced expression of the pre-BCR. As a result, rearrangement of the light-chain loci can proceed (step 3). If this rearrangement is productive, the B cell can synthesize light chains and complete assembly of the B-cell receptor (BCR), which consists of a membrane-bound IgM and associated Igα and Igβ. The B cell is now responsive to antigen-specific stimulation.

Successful rearrangement of V, D, and J segments in the heavy-chain locus thus allows the synthesis of a complete μ chain. B cells at this stage of development are called *pre-B cells*, as they have not yet completed assembly of a functional light-chain gene and therefore cannot engage in antigen recognition. As with other membrane-spanning proteins (see Chapter 13), the μ chain is synthesized in the endoplasmic reticulum. It becomes part of a membrane-bound signaling receptor whose expression is essential for B-cell development to proceed in an orderly fashion.

In pre-B cells, newly made μ chains form a complex with two so-called surrogate light chains, λ5 and VpreB (see Figure 24-19). The μ chain itself possesses a very short (three amino acids) cytosol-facing C-terminal tail and is therefore incapable of recruiting cytoplasmic components for the purpose of signal transduction. Instead, pre-B cells express two auxiliary transmembrane proteins, called *Igα* and *Igβ*, each of which carries in its cytoplasmic tail an *i*mmunoreceptor *t*yrosine-based *a*ctivation *m*otif, or ITAM. The entire complex, including μ chain, λ5, VpreB, Igα, and Igβ, constitutes the *pre-B-cell*

receptor (pre-BCR). Engagement of this receptor by (unknown) suitable signals results in recruitment and activation of a Src-family tyrosine kinase, which phosphorylates tyrosine residues in the ITAMs. In their phosphorylated form, ITAMs recruit other molecules essential for signal transduction (see below). Because no functional light chains are yet part of this receptor, it is presumed to be incapable of antigen recognition, as the antigen-binding site has contributions from both the heavy and light chains (see Figure 24-14) (except in camelids, which produce only H-chain antibodies).

The pre-B-cell receptor has several important functions. First, it shuts off expression of the RAG recombinases, so that rearrangement of the other (allelic) heavy-chain locus cannot proceed. This phenomenon, called *allelic exclusion*, ensures that only one of the two available copies of the heavy-chain locus will be rearranged and thus expressed as a complete μ chain. Second, because of the association of the pre-B-cell receptor with Igα and Igβ, the receptor becomes a functional signal-transduction unit. Signals that emanate from the pre-BCR initiate proliferation of the pre-B cell to expand the numbers of those B cells that have undergone productive D-J and V-D-J recombination.

In the course of this expansion, expression of the surrogate light chains, VpreB and λ5, subsides. The progressive dilution of VpreB and λ5 with every successive cell division results in insufficient fully assembled pre-BCR in the endoplasmic reticulum. As a

consequence, the heavy chains are degraded (see Chapters 13 and 14) and the amount of pre-BCR signaling decreases. This reduction in signaling allows re-initiation of expression of the RAG recombinases, which now target the κ or λ light-chain locus. A productive light-chain V-J rearrangement also shuts off rearrangement of the allelic locus (allelic exclusion). Upon completion of a successful V-J light-chain rearrangement, the B cell can make both μ heavy chains and κ or λ light chains and assemble them into a functional **B-cell receptor (BCR)**, which can recognize antigen (see Figure 24-19).

Once a B cell expresses a complete BCR on its cell surface, it can recognize antigen, and all subsequent steps in B-cell activation and differentiation require engagement with the antigen for which that BCR is specific. The BCR not only plays a role in driving B-cell proliferation upon a successful encounter with antigen, but also functions as a device for receptor-mediated endocytosis, an essential step that allows the B cell to process the acquired antigen and convert it into a signal that sends out a call for assistance by T lymphocytes; this antigen-presentation function of B cells is described in later sections.

During an Adaptive Response, B Cells Switch from Making Membrane-Bound Ig to Making Secreted Ig

As just described, the B-cell receptor, a membrane-bound IgM, provides a B cell with the ability to recognize a particular antigen, an event that triggers clonal selection and proliferation of that B cell, thus increasing the number of B cells specific for that antigen (see Figure 24-12). However, key functions of immunoglobulins, such as neutralization of antigens or killing of bacteria, require that those products be released by the B cell so that they can accumulate in the extracellular environment and act at a distance from the site where they were produced.

Whether to synthesize membrane-bound or secreted immunoglobulin is a choice made by the B cell during processing of the heavy-chain primary transcript. As shown in Figure 24-20, the μ locus contains two exons (TM1 and TM2) that together encode a C-terminal domain that spans the plasma membrane and anchors the IgM in it. One polyadenylation site is found upstream of these exons; a second polyadenylation site is present downstream. If the downstream poly(A) site is chosen, then further processing yields an mRNA that encodes the membrane-bound form of μ. (As described above, this choice is necessary for formation of the B-cell receptor, which includes membrane-bound IgM.) If the upstream poly(A) site is chosen, processing yields the secreted version of the μ chain. Similar arrangements are found for the other Ig constant-region gene segments (γ, α, ε), each of which can specify either a membrane-bound or a secreted heavy chain. The ability to switch between the membrane-anchored and the secreted form of immunoglobulin heavy chains by alternative use of polyadenylation

sites (*not* by alternative splicing) is so far unique to this family of gene products.

FIGURE 24-20 Synthesis of secreted and membrane IgM. The organization of the μ heavy-chain primary transcript is shown at the top: Cμ4 is the exon encoding the fourth μ constant-region domain; μ_s is a coding sequence unique for secreted IgM; TM1 and TM2 are exons that specify the transmembrane domain of the μ chain. Whether secreted or membrane-bound IgM is made depends on which poly(A) site is selected during processing of the primary transcript. (a) If the upstream poly(A) site is used, the resulting mRNA includes the entire Cμ4 exon and specifies the secreted form of the μ chain. (b) If the downstream poly(A) site is used, a splice donor site in the Cμ4 exon allows splicing to the transmembrane exons, yielding an mRNA that encodes the membrane-bound form of the μ chain. Similar mechanisms generate secreted and membrane-bound forms of other Ig isotypes. SS = signal sequence.

The capacity to switch from the synthesis of exclusively membrane-bound immunoglobulin to the synthesis of secreted immunoglobulin is acquired by B cells in the course of their differentiation. Terminally differentiated B cells, called *plasma cells*, are devoted almost exclusively to the synthesis of secreted antibodies (see Figure 24-7). Each plasma cell synthesizes and

secretes several thousand antibody molecules per second. It is this ramped-up production of secreted antibodies that underlies the effectiveness of the adaptive immune response in eliminating a pathogen and protecting against subsequent infection with the same pathogen. The protective value of antibodies is proportional to the concentration at which they are present in the circulation. Indeed, circulating antibody levels are often used as the key parameter to determine whether vaccination against a particular pathogen has been successful. The ability of plasma cells to secrete large amounts of immunoglobulins requires a massive expansion of the endoplasmic reticulum (ER), a hallmark of plasma cells. The unfolded-protein response (see Chapter 13) is initiated in B cells as an essential physiological mechanism to expand the ER and prepare the differentiating B cell for its future task as a highly active secretory cell. Interference with the unfolded-protein response abolishes the ability of B cells to turn into plasma cells.

B Cells Can Switch the Isotype of Immunoglobulin They Make

In the immunoglobulin heavy-chain locus, the exons that encode the constant segments of the μ chain lie immediately downstream of the rearranged VDJ exon (Figure 24-21, *top*). They are followed by exons that specify the constant segments of the δ chain. Transcription of a newly rearranged immunoglobulin heavy-chain

locus yields a single primary transcript that includes both the μ and δ constant regions. The splicing of this large transcript determines whether a μ chain or a δ chain will be produced. Downstream of the μ and δ exons are the exons that encode the constant segments of all the other heavy-chain isotypes. Upstream of each cluster of exons encoding one of the different isotypes (with the exception of the δ locus) is a repetitive sequence (switch region) that is recombination-prone, presumably because of its repetitive nature. Because each B cell necessarily starts out with surface IgM, recombination involving these sites, if it occurs, results in *class switching* from IgM to one of the other isotypes encoded downstream in the array of constant-region genes (Figure 24-21). The intervening DNA is deleted.

FIGURE 24-21 Class-switch recombination in the immunoglobulin heavy-chain locus. Class-switch recombination involves switch sites, which are repetitive sequences (colored circles) upstream of each of the heavy-chain constant-region genes. Recombination requires activation-induced deaminase (AID) as well as cytokines (e.g., IL-4) produced by certain helper T cells. Recombination eliminates the segment of DNA between the switch site upstream of μ exons and the constant region to which switching occurs. Class switching generates antibody molecules with the same specificity for antigen as that of the IgM-

bearing B cell that mounted the original response, but with different heavy-chain constant regions and therefore different effector functions.

In the course of its differentiation, a B cell can switch Ig classes sequentially. Importantly, the light chain is not affected by this process, nor is the rearranged VDJ segment with which the B cell started out on this pathway. Class-switch recombination thus generates antibodies with different constant regions, but identical antigenic specificity because the variable region has not changed. Each immunoglobulin isotype is characterized by its own unique constant region. As discussed previously, these constant regions determine the functional properties of the various isotypes. Class-switch recombination is dependent on the activity of AID and on the presence of antigen as well as on helper T cells. Somatic hypermutation and class-switch recombination occur concurrently, and their combined effect allows fine-tuning of the adaptive immune response with respect to the affinity of the antibodies produced and the effector functions employed.

KEY CONCEPTS OF SECTION 24.3

Generation of Antibody Diversity and B-Cell Development

- Functional antibody-encoding genes are generated by somatic rearrangement of multiple DNA segments at the heavy-chain and light-chain loci. These rearrangements involve V and J segments for immunoglobulin light chains and V, D, and J segments for immunoglobulin heavy chains (see Figure 24-15).
- Rearrangement of immunoglobulin gene segments is controlled by conserved recombination signal sequences (RSSs) composed of heptamers and nonamers

separated by 12- or 23-bp spacers (see Figure 24-16). Only those segments that have spacers of different lengths can rearrange successfully: two segments to be joined must possess a 12- and a 23-bp spacer, not two of identical length.

- The molecular machinery that carries out the rearrangement process includes proteins made only in lymphocytes (recombinases RAG1 and RAG2).
- Antibody diversity is created by the random selection of Ig gene segments to be recombined and by the ability of the heavy and light chains produced from rearranged Ig genes to associate with many different light chains and heavy chains, respectively.
- Junctional imprecision generates additional antibody diversity at the joints of the gene segments brought together by somatic gene rearrangements.
- Further antibody diversity arises after B cells encounter antigen as a consequence of somatic hypermutation, which can lead to the selection and proliferation of B cells producing the highest affinity antibodies, a process termed *affinity maturation*.
- During B-cell development, heavy-chain genes are rearranged first, leading to expression of the pre-B-cell receptor. Subsequent rearrangement of light-chain genes results in assembly of an IgM membrane-bound B-cell receptor (see Figure 24-19).
- Only one of the allelic copies of the heavy-chain locus and of the light-chain locus is rearranged (allelic exclusion), ensuring that a B cell expresses Ig with a single antigenic specificity.
- Polyadenylation at different poly(A) sites in an Ig primary transcript determines whether the membrane-bound or secreted form of an antibody is produced (see Figure 24-20).
- During an immune response, class switching allows B cells to adjust the class of antibody made and thus the effector functions of the immunoglobulins produced, while retaining the antibody's specificity for antigen (see Figure 24-21).

24.4 The MHC and Antigen Presentation

Antibodies can bind their target antigen without the involvement of other molecules; the presence of antigen and antibody is sufficient for their interaction. In the course of their differentiation, B cells receive essential assistance in the form of signals sent from T cells by a process that will be described in some detail below. This process, literally called *T-cell help*, is antigen-specific, and the T cells responsible for providing it are *helper T cells*. Although antibodies contribute to the elimination of bacterial and viral pathogens, it may also be necessary to destroy infected host cells that might serve as a source of new virus particles. This task is carried out by *cytotoxic T cells*.

Both helper T cells and cytotoxic T cells make use of an antigen-specific T-cell receptor on its surface that, as we see in Section 24.5, is encoded by genes that are generated by mechanisms analogous to those used by B cells to generate immunoglobulin genes — including gene rearrangements. However, T cells recognize their cognate antigens in a manner very different from that used by B cells. The antigen-specific receptors on T cells recognize short segments of protein antigens but can do so only when these peptides are noncovalently bound to a glycoprotein complex present on the external surface of an *antigen-presenting cell*. Importantly, each T cell

in an individual expresses many copies of a unique T-cell receptor on its surface, and different T-cell receptors will bind to different sets of peptides bound to the glycoprotein complex on an antigen-presenting cell.

The membrane glycoprotein complex that presents the antigen snippets is encoded in a region of genomic DNA called the *major histocompatibility complex (MHC)*. As we will see in detail, various antigen-presenting cells, in the course of their normal activities, digest pathogen-derived proteins (as well as their own proteins) and then present complexes consisting of an MHC protein bound to a protein snippet (usually a small peptide) on their cell surface. T cells can scrutinize these complexes, and if they detect a pathogen-derived peptide bound to the MHC molecule, the T cells take appropriate action, which may include killing the cell that carries the MHC-peptide complex. In this section, we describe the MHC and the proteins it encodes, then examine how MHC molecules are involved in antigen presentation and antigen recognition by T cells.

The MHC Determines the Ability of Two Unrelated Individuals of the Same Species to Accept or Reject Grafts

The MHC was discovered, as its name implies, as the genetic locus that controls acceptance or rejection of tissue grafts. At a time when

tissue culture had not yet been developed to the stage at which tumor-derived cell lines could be propagated in the laboratory, investigators relied on serial passage of tumor tissue in vivo (i.e., transplanting a tumor from one mouse to another). It was quickly observed that a tumor that arose spontaneously in one inbred strain of mice could be propagated successfully in the strain in which it arose but generally not in a genetically distinct strain of mice. Genetic analysis showed that a single major genetic locus in the recipient mouse was responsible for this behavior. Similarly, transplantation of healthy skin was feasible within the same strain of mice, but not when the recipient was of a genetically distinct background. Genetic analysis of transplant rejection likewise identified a single major locus — the same one responsible for tumor rejection — that controlled acceptance or rejection, which is an immune reaction. This locus has been expanded to the designation MHC to reflect the presence of multiple genes in this region. As we now know, all vertebrates that possess an adaptive immune system have a genetic region that corresponds to the major histocompatibility complex as originally defined in the mouse.

In mice, the genetic region responsible for graft rejection is called the *H-2 complex* (Figure 24-22a). In humans, the genetic region encoding the MHC was uncovered during the study of patients who underwent multiple blood transfusions that provoked an immune response. The human MHC region is called the *HLA complex* (Figure 24-22b). The typical mammalian MHC contains dozens of genes,

many encoding proteins of immunological relevance, not all of which are shown in the figure. All vertebrate MHCs encode a highly homologous set of proteins, although the details of organization and gene content show considerable variation between species, as seen for domestic chickens, mice, and humans. As we will see, several MHC proteins present antigenic peptides for recognition by the immune system. Since most cells in vertebrates express MHC proteins, they therefore have the potential to present antigens — especially antigen derived from pathogenic bacteria and viruses — to the adaptive immune system.

FIGURE 24-22 Organization of the major histocompatibility complex in mice and in humans. The major loci are depicted with schematic diagrams of their encoded proteins below. Class I MHC proteins are composed of an MHC-encoded glycoprotein with a single membrane-spanning sequence, in noncovalent association with a small subunit, called *β2-microglobulin*, which is not encoded in the MHC and is not membrane bound. Class II MHC proteins consist of two nonidentical single-pass transmembrane glycoproteins, both of which are encoded by the MHC.

Interestingly, the human fetus may be considered a tissue graft in the mother: the fetus shares only half of its genetic material with the mother, the other half being contributed by the father. Antigens encoded by the paternal alleles may differ sufficiently from their maternal counterparts to elicit an immune response in the mother. Such a response can occur because in the course of pregnancy, fetal cells that slough off into the maternal circulation can stimulate the maternal immune system to mount an antibody response against the paternal antigens. We now know that these antibodies recognize proteins encoded by the human MHC. The fetus itself is spared rejection because of the specialized organization of the placenta, which prevents initiation of an immune response by the mother against fetal tissue.

The Killing Activity of Cytotoxic T Cells Is Antigen Specific and MHC Restricted

Clearly MHC molecules did not evolve to prevent the exchange of surgical grafts. MHC molecules play an essential role in the recognition of virus-infected cells by a type of T cell termed a *cytotoxic T cell*, which is also called a *cytolytic T lymphocyte (CTL)*. In virus-infected cells, MHC molecules bind to peptides derived from the viral proteins and display these fragments on the cell surface, where CTLs, charged with eliminating the infection, can recognize them. How such fragments of antigen are generated and displayed

will be described below. CTLs that have receptors capable of recognizing a particular peptide-MHC complex unleash a payload of lethal molecules onto the infected target cells, destroying the target-cell membranes. The destruction of these target cells can be readily measured by the release of their cytoplasmic contents when they physically disintegrate. Thus CTL killing of infected host cells requires: (1) MHC presentation of antigenic peptides from the pathogen on the host-cell surface, (2) CTLs expressing antigen-MHC–specific T-cell receptors on their surface that can recognize the MHC-antigen complex, and (3) the activation of the CTL killing machinery once the T-cell receptors have bound to the MHC-antigen complex.

Mice that have recovered from a particular viral infection are a ready source of CTLs that can recognize and kill target cells infected with the same virus. If CTLs are obtained from a mouse that has successfully cleared an infection with influenza virus, cytotoxic activity is observed against influenza-infected target cells, but not against uninfected controls (Figures 24-23a and 24-23b, experiment **2**). Moreover, the influenza-specific CTLs will not kill target cells infected with a different virus, such as vesicular stomatitis virus (Figure 24-23b experiment **3**). CTLs can even discriminate between closely related strains of influenza virus and can do so with pinpoint precision: differences of a single amino acid in the viral antigen may suffice to prevent recognition and killing by CTLs. These experiments show that CTLs are truly antigen specific and do not

simply recognize some attribute that is shared by all virus-infected cells, regardless of the identity of the virus.

EXPERIMENTAL FIGURE 24-23 Chromium (^{51}Cr) release assay allows direct demonstration of the cytotoxicity and specificity of cytotoxic T cells in a heterogeneous population of cells. (a) A suspension of spleen cells containing cytotoxic (killer) T cells is prepared from mice that have been exposed to a particular virus (e.g., influenza virus) and have cleared the infection. Target cells obtained from mice of the same strain are infected with the identical virus or left uninfected. After infection, cellular proteins are labeled

nonspecifically by incubation of the target-cell suspension with ^{51}Cr. When the radiolabeled target cells are incubated with the suspension of cytotoxic T cells, the killing of infected target cells results in release of the ^{51}Cr-labeled proteins. Uninfected target cells are not killed and retain their radioactive contents. Lysis of cells by cytotoxic T cells can therefore be readily detected and quantitated by measuring the radioactivity released into the supernatant. (b) Cytotoxic T cells (CTLs) harvested from mice that have been infected with influenza virus (X) can be tested against various target cells to determine the specificity of CTL-mediated killing. CTLs capable of lysing influenza virus–infected target cells (**1**) cannot kill uninfected cells (**2**) or cells infected with vesicular stomatitis virus (Y), for example (**3**). When these CTLs are tested on influenza virus–infected targets from a strain of mice that carries an altogether different MHC type (strain b, blue target cells), again no killing is observed (**4**). Cytotoxic T-cell activity is thus virus specific and restricted by the MHC.

In the example in Figure 24-23a, we assumed that the CTLs harvested from an influenza-immune mouse are assayed on influenza-infected target cells derived from that same strain of mouse (strain a). However, if target cells from a completely unrelated strain of mouse (strain b, blue-colored target cell in Figure 24-23b experiment **4**) are infected with influenza and used as targets, the CTLs from the strain a mouse are unable to kill the infected strain b target cells (Figure 24-23b, **1** vs. **4**). It is therefore not sufficient that the antigen (an influenza-derived protein) is present; recognition of the antigen by CTLs is *restricted* by mouse strain-specific elements. Genetic mapping has shown that these restricting elements are encoded by genes in the MHC. Thus CTLs from a mouse strain that is immune to influenza will kill influenza-infected target cells from another mouse strain only if the two strains match at the MHC loci for the relevant MHC molecules.

This phenomenon is therefore known as *MHC restriction*, and the MHC molecules involved are called *restriction elements*.

T Cells with Different Functional Properties Are Guided by Two Distinct Classes of MHC Molecules

The MHC encodes two types of glycoproteins essential for immune recognition, commonly called *class I* and *class II MHC molecules*. The genetic maps of mouse and human MHCs show the presence of several class I MHC genes and several class II MHC genes, although their arrangements differ between the two species (see Figure 24-22). In addition to class I and class II MHC molecules, the MHC encodes key components of the antigen-processing (e.g., proteolysis) and presentation machinery. Finally, the typical vertebrate MHC also encodes components of the complement cascade.

Both class I and class II MHC proteins are involved in presenting antigen to T cells, but they serve two broadly distinct functions. Class I MHC products present antigens to cytotoxic T cells, licensing them to destroy infected cells. Cytotoxic T cells are characterized by the expression of CD8, a surface glycoprotein that determines the ability of the T cells that carry it to interact with class I MHC products. Most, if not all, nucleated cells constitutively express class

I MHC molecules, and many can support replication of viruses. Cytotoxic T cells thus recognize and kill infected cells of all body types via cell-surface class I MHC molecules that have bound to it (display) a virus-derived antigen (peptide).

Class II MHC products are found exclusively on specialized antigen-presenting cells (APCs), also called *professional* APCs. These APCs present antigens bound to class II MHC molecules to a class of T lymphocytes called *helper T cells*. This presentation is the start of an adaptive immune response that also enables cytotoxic T cells to kill their targets and assists B cells in producing antigen-specific antibodies. B cells cannot undergo final differentiation into antibody-secreting plasma cells without assistance from helper T cells. Helper T cells express a surface glycoprotein called *CD4* and interact with class II but not class I MHC molecules on target cells. The constitutive expression of class II MHC molecules is confined to professional APCs, which include B cells, dendritic cells, and macrophages. (Several other cell types, such as some epithelia, can be induced to express class II MHC molecules under specific circumstances, but we will not discuss them.) Again, the underlying cell biology that describes the expression, assembly, and mode of antigen presentation by class II MHC molecules fits this functional specialization rather neatly, as we shall see below.

The two major groups of functionally distinct T lymphocytes — cytotoxic T cells and helper T cells — can thus be distinguished by

the unique profile of membrane proteins displayed at their cell surface and by the MHC molecules they use as targets; these targets are often referred to as *restriction elements*.

- Cytotoxic T cells: CD8 marker; class I MHC restricted
- Helper T cells: CD4 marker; class II MHC restricted

Both CD4 and CD8, along with many other proteins of the immune system, including B-cell and T-cell receptors and the polymeric IgA receptor, belong to the immunoglobulin (Ig) superfamily of proteins, all of which have one or more Ig domains. The molecular basis for the strict correlation between expression of CD8 and use of class I MHC molecules as the restriction element, or between expression of CD4 and use of class II MHC molecules as the restriction element, will become evident once the structure and mode of action of MHC molecules has been described.

MHC Molecules Are Highly Polymorphic, Bind Peptide Antigens, and Interact with the T-Cell Receptor

Polymorphisms in the MHC Locus Are the Basis of Transplant Rejection

Both class I and class II MHC molecules are highly *polymorphic*; that is, thousands of allelic variants, encoding similar proteins but with slightly different amino acid sequences, exist among individuals of the same species. The vertebrate immune system can respond to these allelic differences, and its ability to recognize allelic MHC variants is the underlying immunological cause for rejection of transplants that involve unrelated, genetically distinct individuals.

The two classes of MHC molecules are structurally similar in many respects, as are their interactions with peptides and the T-cell receptor. MHC molecules are particularly important for recognizing self tissue and distinguishing it from nonself (and thus possibly pathogenic) substances. In general, except for close relatives, any two individuals have a very low chance of sharing the same MHC variants. Any inter-individual differences in MHC molecules in a graft recipient and donor will be recognized by the recipient's immune system, which will treat the graft as foreign and eliminate it (graft rejection). The greater the similarity in the set of MHC alleles of a donor and a transplant recipient, the greater the chance that the transplant will be accepted. This is why surgeons look for an MHC-matched individual to donate an organ. If the tissue type (MHC alleles) of the donor does not exactly match that of the recipient, it is necessary to use drugs that suppress the immune responses of the recipient to prevent organ rejection.

The cell-biological mechanisms by which the immune system develops the capacity to distinguish self from nonself (or nonpathogenic from pathogenic) are complex, yet worth understanding. Understanding the molecular and cellular basis of immunity has enormous practical consequences for medicine and public health. We will therefore consider these molecular and cellular mechanisms in detail, beginning with the structures of the MHC proteins and the way by which peptides become bound to them.

Class I MHC Molecules

Class I MHC molecules, which belong to the Ig superfamily, consist of two polypeptide subunits. The larger subunit, for which there are multiple independent gene copies in the MHC region of mammalian genomes, is a type I membrane glycoprotein (see Figure 13-10). The smaller β2-microglobulin subunit is not encoded by the MHC and corresponds in structure to an Ig domain. The larger subunits of class I MHC molecules in humans are encoded by the HLA-A, HLA-B, and HLA-C loci (see Figure 24-22). In the mouse, the larger subunits of class I MHC molecules are encoded by the H-2K, H-2D, and H-2L loci.

The three-dimensional structure of a class I MHC molecule shows two Ig-like domains (Figure 24-24a). These domains support an eight-stranded β sheet topped by two α helices. Jointly, the β sheet and the helices create a cleft, closed at both ends, in which a peptide

binds. The mode of peptide binding by a class I MHC molecule requires that the peptide be about 8–10 amino acids long, so that the ends of the peptide can be tucked into pockets that accommodate the charged amino and carboxyl groups at the termini of the peptide. Further, the peptide is anchored into the peptide-binding cleft by means of a small number of amino acid side chains, each of which is accommodated by a pocket in the MHC molecule that neatly fits that particular anchor amino acid residue (Figure 24-25a). On average, two such specificity pockets must be filled correctly to allow stable peptide binding, restricting binding to peptides with side chains that can fit into these pockets. In this manner, a given MHC molecule can accommodate a large number of peptides of diverse, yet circumscribed, sequence.

FIGURE 24-24 Three-dimensional structure of class I and class II MHC molecules. (a) Shown here is the structure of a class I MHC molecule with a bound antigenic (HA) peptide as determined by x-ray crystallography. The portion of a class I MHC molecule that binds a peptide consists of a β sheet composed of eight β strands and flanked by two α helices. The peptide-binding cleft is formed entirely from the MHC-encoded large subunit, which associates noncovalently with the small subunit (β2-microglobulin). (b) Class II MHC molecules are structurally similar to class I molecules but with several important distinctions. Both the α and β subunits of class II MHC molecules are MHC encoded and contribute to formation of the peptide-binding cleft. The peptide-binding cleft of class II MHC molecules accommodates a wider range of peptide sizes than that of class I molecules. Both class I and class II MHC proteins span the cell membrane, and each includes a transmembrane segment and a cytoplasmic tail (see Figures 24-21, 24-26, and 24-29). These are not included in the crystallographic analysis and are not shown in the figure.

FIGURE 24-25 Peptide binding and restriction in class I MHC. (a) Peptides that bind to class I molecules are on average 8–10 residues in length, require proper accommodation of the termini, and include two or three residues that are conserved (anchor residues). Amino acid residues in class I molecules that distinguish one allele from another (polymorphic residues) occur in and around the peptide-binding cleft. The polymorphic residues in the MHC affect both the specificity of peptide binding and interactions with T-cell receptors. Successful recognition of an antigenic peptide–MHC complex by a T-cell receptor requires a good fit among the receptor, peptide, and MHC molecule. (b) Steric clash and a lack of complementarity between anchor residues and the MHC molecule, and a similar clash between the T-cell receptor and the MHC molecule, prevent proper binding. Each T cell in an individual expresses one type of T-cell receptor, one that is thus restricted to binding specific peptide-MHC complexes.

The polymorphic residues that distinguish one allelic MHC molecule from another are located mainly in and around the peptide-binding cleft. These residues therefore determine the architecture of the peptide-binding pocket and hence the specificity of peptide binding. Further, these polymorphic residues affect the surface of the MHC molecule that makes contact with the T-cell receptor. A T-cell receptor that can interact with one particular class I MHC allele will therefore, as a rule, not interact with unrelated MHC molecules because of their different surface architectures (Figure 24-25b); this is the molecular basis of MHC restriction. The CD8 molecule on cytotoxic T cells functions as a co-receptor,

binding to conserved portions of the class I MHC molecule. The presence of CD8 thus sets the class I MHC preference of any mature T cell that bears it.

Class II MHC Molecules

The two subunits (α and β) of class II MHC molecules are both type I membrane glycoproteins of the Ig superfamily. The typical mammalian MHC contains several loci that encode class II MHC molecules (see Figure 24-22). Like the large subunit of class I molecules, both the α and β subunits of class II molecules show genetic polymorphism.

The basic three-dimensional design of class II MHC molecules resembles that of class I MHC molecules. Two membrane-proximal Ig-like domains support a peptide-binding portion with a peptide-binding cleft (see Figure 24-24b). In class II MHC molecules, the α and β subunits contribute equally to the construction of the peptide-binding cleft. This cleft is open at both ends and thus supports the binding of peptides longer than those that bind to class I MHC molecules because the peptides can protrude from both ends of the cleft. The mode of peptide binding involves pockets that accommodate specific amino acid side chains as well as contacts between side chains of the MHC molecule and main-chain atoms of the bound peptide. As for class I MHC, class II MHC polymorphisms mainly affect residues in and around the peptide-binding cleft, so that peptide-binding specificity usually differs among different

allelic products. A T-cell receptor that interacts with a particular class II MHC molecule will not, as a rule, interact with a different class II MHC allelic variant, not only because of the difference in the peptide-binding specificity of the allelic MHC molecules, but also because of the polymorphisms that affect the residues that contact the T-cell receptor. Class I MHC is the basis for class II MHC restricted recognition of antigens. As we saw for class I MHC molecules and their CD8 co-receptor, the CD4 co-receptor recognizes conserved features on class II MHC molecules. Any mature T cell that bears the CD4 co-receptor uses class II MHC molecules for antigen recognition.

As we will see below, class II MHC molecules evolved to present peptides generated predominantly in endosomes and lysosomes. Peptide binding to a class II MHC molecule takes place in those organelles, and class II MHC molecules are targeted specifically to those locations after their synthesis in the endoplasmic reticulum. This targeting is accomplished by means of a chaperone called the *invariant chain*, a type II membrane glycoprotein (see Figure 13-10). The invariant chain, termed *Ii*, plays a key role in the early stages of class II MHC biosynthesis by forming in the endoplasmic reticulum a trimeric structure onto which three newly made class II MHC αβ heterodimers assemble. The final assembly product thus consists of nine polypeptides: $(\alpha\beta Ii)_3$. The interaction between Ii and the αβ heterodimer involves a stretch of Ii, called the *CLIP segment*, which occupies the class II MHC peptide-binding cleft. Once the $(\alpha\beta Ii)_3$

complex is assembled, the complex enters the secretory pathway and is diverted to endosomes and lysosomes at the *trans*-Golgi network (see Figure 14-2). The signals for this diversion are carried by the Ii cytoplasmic tail.

In Antigen Presentation, Protein Fragments Are Complexed with MHC Products and Posted to the Cell Surface

The process by which foreign materials enter the immune system is the key step that determines the eventual outcome of an immune response. A successful adaptive immune response, which includes the production of antibodies and the generation of helper and cytotoxic T cells, absolutely requires the involvement of professional APCs. These cells are what acquire antigen, process it and then display it in a form that can be recognized by T cells. The pathway that converts antigen into a form suitable for T-cell recognition is referred to as **antigen processing and presentation**.

The class I MHC pathway focuses predominantly on presentation of fragments of proteins synthesized by the cell itself (including pathogen-encoded proteins found inside the infected cells), whereas the class II MHC pathway is centered on materials acquired from outside the APC. Recall that all nucleated cells express class I MHC

products or can be induced to do so. This makes sense in view of the fact that a nucleated cell is capable of synthesizing nucleic acids and proteins and can thus in principle sustain replication of a viral pathogen. The ability to alert the immune system to the presence of an intracellular invader is inextricably linked to class I MHC-restricted antigen presentation. The distinction between the presentation of materials synthesized by an APC itself and the processing and presentation of antigen acquired from outside the cell is by no means absolute. Together, the class I and class II pathways of antigen processing and presentation sample all of the cellular and external compartments that need to be surveyed for the presence of pathogens.

Antigen processing and presentation in both the class I and class II pathways may be divided into six discrete steps that are useful in comparing the two pathways: (1) acquisition of antigen, (2) tagging the antigen for destruction, (3) proteolysis, (4) delivery of peptides to MHC molecules, (5) binding of peptide to an MHC molecule, and (6) display of the peptide-loaded MHC molecule on the cell surface. Here we describe the molecular details of each pathway.

The Class I MHC Pathway Presents Cytosolic Antigens

Figure 24-26 summarizes the six steps in the class I MHC pathway using a virus-infected cell as an example.

FIGURE 24-26 Class I MHC pathway of antigen processing and presentation. Step 1: Acquisition of antigen is synonymous with the production of proteins with errors (e.g., premature termination, misincorporation) or the production of pathogen-derived proteins. Step 2: Dysfunctional proteins are targeted for degradation by ubiquitinylation. Step 3: Proteolysis is carried out by the proteasome. In cells exposed to interferon γ, the

catalytically active β subunits of the proteasome are replaced by interferon-induced immune-specific β subunits. Step 4: Peptides are delivered to the interior of the endoplasmic reticulum (ER) via the dimeric TAP peptide transporter. Step 5: Each peptide is loaded onto a newly made class I MHC molecule within the peptide-loading complex. Step 6: The fully assembled class I MHC–peptide complex is transported to the cell surface via the secretory pathway. See text for details.

1. *Acquisition of Antigen:* In the case of a viral infection, acquisition of antigen is usually synonymous with the infected state. Viruses rely on the host protein synthesis apparatus to generate new viral proteins. Protein synthesis, unlike DNA replication, is an error-prone process, in which a fraction of newly initiated polypeptide chains are terminated prematurely or suffer from other errors (e.g., misincorporation of amino acids, frameshifts, improper or delayed folding). These mistakes in protein synthesis affect the host cell's own proteins and those specified by viral genomes equally. Such error-containing proteins must be rapidly removed so as not to clog up the cytoplasm, engage partner proteins in nonproductive interactions, or even act as dominant negative versions of a protein. Properly folded proteins may also sustain damage that leads to their unfolding, completely or in part, and necessitates their removal. These proteins are an important source of the peptides destined for presentation by class I MHC molecules. With the exception of a specialized process called *cross-presentation* (discussed below), the class I MHC pathway results in the formation of peptide-MHC complexes in which the peptides are derived from proteins synthesized by the class I MHC-bearing cell itself.

2. *Targeting Antigen for Destruction:* For the most part, polyubiquitinylation is responsible for targeting a protein for destruction (see Section 3.4). Polyubiquitinylation is a covalent modification that is tightly regulated.
3. *Proteolysis:* Polyubiquitinylated proteins are destroyed by proteolysis in proteasomes. The proteasome is a protease that engages its substrates and, without the release of intermediates, yields peptides in the size range of 3–20 amino acids as its final digestion products (see Figure 3-32). During the course of an inflammatory response and in response to interferon γ, the three catalytically active β subunits (β1, β2, β5) of the proteasome can be replaced by three immune-specific subunits: β1i, β2i, and β5i, subunits that are encoded in the MHC region of the genome. The net result of this replacement is the generation of an *immunoproteasome*, the output (length of peptide products) of which is matched to the requirements for peptide binding by class I MHC molecules. The immunoproteasome adjusts the average length of the peptides produced, as well as the sites at which cleavage occurs. Given the central role of the proteasome in the generation of the peptides presented by class I MHC molecules, proteasome inhibitors interfere potently with antigen processing via the class I MHC pathway.
4. *Delivery of Peptides to Class I MHC Molecules:* Protein synthesis, polyubiquitinylation, and proteasomal proteolysis all occur in the cytosol, whereas peptide binding by class I MHC molecules occurs in the lumen of the endoplasmic reticulum (ER). Thus peptides must cross the ER membrane to gain access to the

peptide-binding sites of newly made class I molecules, a process mediated by the heterodimeric TAP complex, a member of the ABC superfamily of ATP-powered pumps (see Figure 11-15). The TAP complex binds peptides on the cytoplasmic face of the ER and, in a cycle that includes ATP binding and hydrolysis, translocates them into the ER. The specificity of the TAP complex is such that it can transport only a subset of all cytosolic peptides, primarily those in the length range of 5–10 amino acids, that are compatible with the circumscribed length of peptides that can fit into the class I MHC molecules. The mouse TAP complex shows a pronounced preference for peptides that with C-terminal leucine, valine, isoleucine, or methionine residues match the binding preference of class I MHC molecules. The genes encoding the TAP1 and TAP2 subunits composing the TAP complex are located in the MHC region. Peptidases in the cytosol and in the lumen of the ER may further modify the products of proteasomal proteolysis.

5. *Binding of Peptides to Class I MHC Molecules:* Within the ER, newly synthesized class I MHC molecules are part of a multiprotein complex referred to as the *peptide-loading complex* (Figure 24-27). This complex includes two chaperones (calnexin and calreticulin) and the oxidoreductase ERp57. Another chaperone (tapasin) interacts with both the TAP complex and the class I MHC molecule about to receive peptide. The physical proximity of TAP and the class I MHC molecule is maintained by tapasin. Once peptide loading onto the class I MHC molecule has occurred, a conformational change releases the loaded

class I MHC molecule from the peptide-loading complex. This arrangement effectively ensures that only peptide-loaded class I MHC molecules are released from the ER and then transported to and displayed at the cell surface. The overall efficiency of this pathway is such that approximately 4000 molecules of a given protein must be destroyed to generate a single MHC-peptide complex carrying a peptide from that particular polypeptide.

FIGURE 24-27 Class I MHC peptide-loading complex. The peptide-loading complex comprises not only the Class I MHC molecule that is about to receive a peptide, but

also the TAP-associated protein tapasin, the chaperone calreticulin, and the oxidoreductase ERp57. Tapasin maintains the Class I MHC molecule in a peptide-receptive state and also provides a physical connection with the *t*ransporter associated with *a*ntigen *p*resentation (TAP; not present in this structural diagram). Upon binding of peptide, the Class I MHC molecule is released from the peptide-loading complex and enters the secretory pathway to reach its destination, the cell surface.

6. *Display of Class I MHC–Peptide Complexes at the Cell Surface:* Once peptide loading is complete, the class I MHC–peptide complex is released from the peptide-loading complex and enters the constitutive secretory pathway (see Figure 14-2). Transfer from the Golgi to the cell surface is rapid and completes the biosynthetic pathway of a class I MHC–peptide complex.

The entire sequence of events in the class I pathway occurs constitutively in all nucleated cells, all of which express class I MHC molecules and the other required proteins or can be induced to do so. As we have seen, exposure to cytokines such as interferon γ can induce immune-specific proteasomal subunits to generate immunoproteasomes with enhanced ability to produce the appropriate peptides for presentation by class I MHC molecules. In the absence of a viral infection, protein synthesis and proteolysis continuously generate a stream of peptides that are loaded onto class I MHC molecules. Healthy, normal cells therefore display on their surfaces a representative selection of peptides derived from their own proteins. There may be several thousand distinct MHC-peptide combinations displayed at the surface of a typical nucleated

cell. The display of MHC–self-peptide complexes on the surfaces of normal, uninfected cells plays an essential role in the immune system. It is not until a virus makes its appearance that virus-derived peptides begin to make a contribution to the display of peptide-MHC complexes on cell surfaces.

As we noted above, a properly functioning immune system must be able to distinguish self (nonpathogenic) antigens from nonself (foreign, potentially pathogenic) antigens. The small organ called the *thymus* — located near the sternum at the level of the heart in humans — plays a critical role in controlling the ability of the immune system to identify self and nonself. Developing T cells in the thymus, referred to as *thymocytes*, calibrate their antigen-specific receptors to the sets of MHC-peptide complexes generated on thymic epithelial cells. The display of self peptides by self-MHC molecules in the thymus enables each developing T cell to learn which peptide-MHC combinations are self-derived and must therefore be ignored to avoid a self-destructive autoimmune reaction. T-cell development is thus driven by self-MHC molecules loaded with self peptides, a template on which a useful repertoire of T cells can be molded. Simply put, any T cell that bears a receptor that too strongly reacts with self-MHC–self-peptide complexes is potentially dangerous when it leaves the thymus, and it must be eliminated. This process of selection will be discussed below.

An exception to the usual mode of antigen presentation that is nonetheless crucial in the development of cytotoxic T cells is *cross-presentation*. This term refers to the acquisition by dendritic cells of apoptotic cell remnants, complexes composed of antigen bound to antibody, and possibly other forms of antigen, by phagocytosis. By a pathway that has yet to be fully understood, these materials escape from phagosomal or endosomal compartments into the cytosol, where they are then handled according to the steps described above, resulting in fragments loaded onto class I MHC proteins. Endosomal or lysosomal proteolysis may likewise generate peptides that find their way onto class I MHC proteins, either in the endocytic compartments themselves, or following delivery to the cytosol, where they may enter the canonical class I processing and presentation pathway. Dendritic cells are the most efficient at cross-presentation and so allow the loading of class I MHC molecules complexed with peptides that derive from cells other than the APC itself.

The Class II MHC Pathway Presents Antigens Delivered to the Endocytic Pathway

Although class I MHC and class II MHC molecules show a striking structural resemblance, the manner in which the two classes acquire peptide and their function in antigen recognition differ

greatly. Whereas the primary function of class I MHC molecules is to guide CD8-bearing cytotoxic T cells to their target (usually infected) cells, class II MHC molecules serve to guide CD4-bearing helper T cells to the cells with which they interact, primarily professional APCs. Activated helper T cells provide protection not only by helping B cells to produce antibodies, but also by means of the complex sets of cytokines they produce, which activate phagocytic cells to clear pathogens or help set up an inflammatory response.

As noted previously, class II MHC molecules are expressed primarily by professional APCs: dendritic cells and macrophages, which are phagocytic, and B cells, which are not. Hence the class II MHC pathway of antigen processing and presentation generally occurs only in these cells. The steps in this pathway are depicted in Figure 24-28.

FIGURE 24-28 Class II MHC pathway of antigen processing and presentation. Step 1: Particulate antigens are acquired by phagocytosis and nonparticulate antigens by pinocytosis or endocytosis. Step 2: Exposure of antigen to the acidic and reducing environment of endosomes and lysosomes prepares the antigen for proteolysis. Step 3: The antigen is broken down by various proteases in endosomal and lysosomal compartments. Step 4: Class II MHC molecules, assembled in the ER from their subunits, are delivered to endosomal and lysosomal compartments by means of signals contained in the associated invariant (Ii) chain. This delivery targets late endosomes, lysosomes, and early endosomes, ensuring that class II MHC molecules are exposed to the products of proteolytic breakdown of antigen along the entire endocytic pathway. The Ii polypeptide is degraded in this compartment, followed by removal of Ii remnants in exchange for other peptides destined for presentation. Step 5: Peptide loading is accomplished with the

assistance of DM, a class II MHC–like chaperone protein. Step 6 : Peptide-loaded class II MHC molecules are transported to the cell surface. See text for details.

1. *Acquisition of Antigen:* In the class II MHC pathway, antigen is acquired by pinocytosis, phagocytosis, or receptor-mediated endocytosis. Pinocytosis, which is rather nonspecific, involves the delivery, by a process of membrane invagination and subsequent vesicle fusion, of a volume of extracellular fluid and the molecules dissolved therein. Phagocytosis, the ingestion of particulate materials such as bacteria, viruses, and remnants of dead cells, involves extensive remodeling of the actin-based cytoskeleton to accommodate the incoming particle. Although phagocytosis may be initiated by specific receptor-ligand interactions, these are not always required: even latex particles and other particulates such as glass beads can be ingested very efficiently by macrophages. Pathogens decorated (opsonized) by antibodies and certain complement components are targeted to macrophages and dendritic cells, which recognize them by means of cell-surface receptors for complement components or for the Fc portion of immunoglobulins. The cells then phagocytose them (Figure 24-29). Macrophages and dendritic cells also express several types of less-selective receptors (e.g., C-type lectins, Toll-like receptors, scavenger receptors) that recognize molecular patterns in both soluble and particulate antigens. These cells then internalize the bound antigens by receptor-mediated endocytosis. B cells, which are not phagocytic, can also acquire antigens by receptor-mediated endocytosis using their antigen-specific B-cell receptors (Figure

24-30). Finally, cytosolic antigens may enter the class II MHC pathway via autophagy (see Figure 14-34).

FIGURE 24-29 Presentation of opsonized antigen by phagocytic cells. By means of Fc receptors such as FcγR displayed on their cell surface, specialized phagocytic cells such as macrophages or dendritic cells can bind and ingest pathogens that have been decorated with antibodies (opsonization). After digestion of the phagocytosed particle (e.g., immune complex, bacterium, virus), some of the peptides produced, including fragments of the pathogen (orange), are loaded onto class II MHC molecules (green). Class II MHC–peptide complexes displayed at the surface allow activation of T cells whose receptors are specific for these MHC-peptide combinations. Lipid antigens are delivered to the class I MHC–like molecule CD1 (pink), whose binding site is specialized to accommodate lipids. Certain pathogen-derived peptides (purple) may be delivered to class I MHC products (blue) by means of cross-presentation. The molecular mechanisms that underlie cross-presentation remain to be clarified.

FIGURE 24-30 Antigen presentation by B cells. B cells bind antigen, even if present at low concentration, to their B-cell receptors, or surface Ig. The immune complex that results is internalized and then delivered to endosomal or lysosomal compartments,

where it is degraded. Peptides liberated from the immune complex, including fragments of the protein antigen, are displayed as class II MHC–peptide complexes at the cell surface. Helper T cells specific for the displayed complex can now provide help to the B cell, allowing it to proliferate and eventually form antibody-secreting plasma cells. This help is MHC restricted and antigen specific.

2. *Targeting Antigen for Destruction:* Proteolysis is required to convert intact protein antigens into peptides of a size suitable for binding to class II MHC molecules. Protein antigens are targeted for degradation by progressive unfolding, brought about by the drop in pH as proteins progress along the endocytic pathway. The pH of the extracellular environment is around pH 7.2, while in early endosomes it is between pH 6.5 and 5.5; in late endosomes and lysosomes the pH may drop to pH 4.5. ATP-powered V-class proton pumps in the endosomal and lysosomal membranes are responsible for this acidification (see Figure 11-9). Proteins that are stable at neutral pH tend to unfold when they are exposed to extremes of pH through rupture of hydrogen bonds and destabilization of salt bridges. Furthermore, the environment in the endosomal or lysosomal compartment is a reducing one, in which lysosomes attain a concentration of reducing equivalents in the millimolar range. Reduction of the disulfide bonds that stabilize many extracellular proteins can also be catalyzed by a thioreductase inducible by exposure to interferon γ. The combined action of low pH and reducing environment prepares the antigens for proteolysis.

3. *Proteolysis:* Degradation of proteins in the class II MHC pathway is carried out by a large set of lysosomal proteases, collectively referred to as *cathepsins*, which are either cysteine or aspartyl proteases. A wide range of peptide fragments is produced, including some that can bind to class II MHC molecules. The lysosomal proteases operate optimally at the acidic pH within lysosomes. Consequently, agents that inhibit the activity of the V-class proton pumps that maintain their acidification interfere with antigen processing, as do inhibitors of lysosomal proteases.
4. *Encounter of Peptides with Class II MHC Molecules:* Recall that most class II MHC molecules synthesized in the endoplasmic reticulum are directed to late endosomes. The peptides generated by proteolysis thus reside in the same intracellular space as the class II MHC molecules themselves — they do not have to cross a membrane, as is the case for peptides destined to bind to class I MHC molecules (see Figure 24-26). To allow peptides and class II MHC molecules to meet, the $(\alpha\beta Ii)_3$ complex is transported from the endoplasmic reticulum via the secretory pathway to endosomal compartments.
5. *Binding of Peptides to Class II Molecules:* The $(\alpha\beta Ii)_3$ complex delivered to endosomal compartments is incapable of binding peptide because the peptide-binding cleft in the class II molecule is occupied by the invariant chain (Ii). For the same reason, newly assembled $(\alpha\beta Ii)_3$ complexes do not compete for class I MHC–destined peptides delivered to the ER via TAP: their peptide-binding site is already occupied by Ii. Recall that the ER is where both class I and class II MHC molecules are assembled.

The presence of Ii in the nascent class II MHC complex ensures that class II MHC molecules do not bind peptide in the ER. The same proteases in endosomes and lysosomes that act on internalized antigens and degrade them into peptides also act on the $(\alpha\beta Ii)_3$ complex, resulting in removal of the Ii molecule from the complex, with the exception of a small portion of Ii called the *CLIP segment*. Because it is firmly lodged in the class II MHC peptide-binding cleft, CLIP is resistant to proteolytic attack. The class II MHC molecules themselves are also resistant to unfolding and proteolytic attack under the harsh conditions that prevail in the endocytic pathway. Next the CLIP segment is removed from the αβ heterodimer by the chaperone DM, and the newly vacated peptide-binding cleft of the class II MHC molecule may now bind the peptides that are abundantly present in the endocytic pathway. Although the DM protein is MHC encoded and structurally very similar to class II molecules, it does not itself bind peptides. However, newly formed class II MHC–peptide complexes are themselves susceptible to further editing by DM, which may dislodge the peptide already bound, until the class II molecule acquires a peptide that binds so strongly that it cannot be removed by DM. The resulting class II MHC–peptide complexes are extremely stable, with estimated half-lives far in excess of 24 hours.

6. *Display of Class II MHC–Peptide Complexes at the Cell Surface:* The newly generated class II MHC–peptide complexes are localized mostly in late endosomal compartments, which include multivesicular endosomes (or bodies) (see Figure 14-32). Endosomal compartments then elongate and ultimately deliver

class II MHC–peptide complexes to the surface by membrane fusion. These events are tightly regulated: tubulation and delivery of class II MHC molecules to the surface are enhanced in dendritic cells and macrophages following their activation by signals generated in response to infection, such as bacterial lipopolysaccharide, which is detected by Toll-like receptors on the surfaces of these professional APCs, as well as inflammatory cytokines, such as interferon γ, produced by CD4-expressing helper T cells.

For professional APCs, the above steps are constitutive — they happen all the time — but they can be modulated by exposure to microbial agents and cytokines. In addition to the pathways described here for class I and class II MHC products, there is a category of class I MHC–related molecules, the CD1 proteins, that are specialized in the presentation of lipid antigens. The structure of a CD1 molecule resembles that of a class I MHC molecule: a larger subunit complexed with β2-microglobulin. Many species of bacteria produce lipids whose chemical structures are not found in their mammalian hosts. These lipids can serve as antigens when presented by CD1 molecules (see Figure 24-29), to which they bind via a lipid-binding pocket that is conceptually similar to that of most MHC molecules. Signals in the cytoplasmic tail of the larger CD1 subunit target these molecules to endosomal or lysosomal compartments, where loading with antigenic lipids occurs. The CD1-lipid complexes engage a relatively rare class of T cells, referred to as *NKT cells*, as well as *γδ T cells*, both described below. NKT cells

fulfill an important role in cytokine production and help initiate and orchestrate adaptive immune responses via their cytokine outputs. Other proteins structurally related to Class I MHC products such as the MR1 protein can bind small metabolites and present them to a special subset of T lymphocytes called *MAIT cells*.

KEY CONCEPTS OF SECTION 24.4

The MHC and Antigen Presentation

- The MHC, discovered as the genetic region responsible for acceptance or rejection of grafts, encodes many different proteins involved in the immune response. Two of these proteins, class I and class II MHC molecules, are highly polymorphic, occurring in many allelic variations (see Figure 24-22).
- The function of the class I and class II MHC proteins is to bind peptide antigens and display them on the surfaces of cells so that the antigen–MHC protein complex can interact with antigen-specific T-cell receptors on T cells. When an antigen–MHC protein complex on an antigen-presenting cell binds to its complementary T-cell receptor on a T cell, the T cell is activated to assume effector functions, such as the production of cytokines or the ability to kill a virus-infected cell. Class I MHC molecules are found on most nucleated cells, whereas the expression of class II MHC molecules is confined largely to professional APCs such as dendritic cells, macrophages, and B cells.
- The organization and structure of class I and class II MHC molecules is similar and includes a peptide-binding cleft that is specialized for binding a wide variety of peptides (see Figure 24-24).
- Different allelic variants of MHC molecules bind different sets of peptides because the differences that distinguish one allele from another include residues that define the architecture of the peptide-binding cleft (see Figure 24-25). Allelic variation also includes residues in the MHC molecule that directly contact the corresponding T-cell receptor. Thus different allelic variants of an MHC molecule, even if they bind the identical peptide, do not usually react with the same T-cell receptor. This phenomenon is called *MHC restriction*.
- Peptide binding by class I and class II MHC molecules occurs in different intracellular compartments: class I molecules bind predominantly to cytosolic materials, whereas

class II molecules bind to extracellular materials internalized by phagocytosis, pinocytosis, or receptor-mediated endocytosis.

- The process by which protein antigens are acquired, processed into peptides, and converted into surface-displayed MHC-peptide complexes is referred to as *antigen processing and presentation*. This process operates continuously in cells that express the relevant MHC molecules, yet can be modulated in the course of an immune response.
- Antigen processing and presentation can be divided into six discrete steps: (1) acquisition of antigen; (2) targeting of the antigen for destruction; (3) proteolysis; (4) encounter of peptides with MHC molecules; (5) binding of peptides to MHC molecules; and (6) display of the peptide-loaded MHC molecules on the cell surface (see Figures 24-25 and 24-27).

24.5 T Cells, T-Cell Receptors, and T-Cell Development

T lymphocytes recognize antigen through specific interactions of their receptors with MHC molecules. The diverse, antigen-specific T-cell receptors made by individual T cells that are entrusted with this task are structurally related to the F(ab) portion of immunoglobulins. To generate a large repertoire of antigen-specific T-cell receptors, T cells rearrange the genes encoding the T-cell receptor subunits by mechanisms of somatic recombination essentially identical to those used by B cells to rearrange immunoglobulin genes. The development of T cells, like that of B cells, is strictly dependent on successful completion of these somatic gene rearrangements to yield a functional T-cell receptor. Genetic ablation of RAG activity eliminates all of the T cells as well as all of the antibody-producing B cells. As noted previously, each T cell expresses a single type of T-cell receptor. In this section, we describe the receptor subunits that mediate antigen-specific recognition, how they pair up with membrane glycoproteins essential for signal transduction, and how these complexes recognize MHC-peptide combinations.

As pointed out in the preceding section, an individual's T cells recognize peptide antigens only when they are bound to the polymorphic MHC molecules present in that individual. In the course of T-cell development, T cells must learn the identity of these

self MHC molecules and receive instructions about which MHC-peptide combinations to ignore, so as to avoid autoimmunity: the potentially catastrophic reactions of newly generated T cells with the individual's own tissues.

The Structure of the T-Cell Receptor Resembles the F(ab) Portion of an Immunoglobulin

Much as B cells use the B-cell receptors on their surfaces to recognize antigens and generate intracellular signals that lead to clonal expansion, T cells depend on their **T-cell receptors (TCRs)** to initiate their participation in immune responses. T cells that have been activated via these antigen-specific receptors proliferate and acquire the capacity to kill antigen-bearing target cells (in the case of cytotoxic T cells) or to secrete cytokines that will assist B cells in their differentiation into antibody-producing plasma cells (in the case of helper T cells). The TCR recognizes antigenic peptides bound to MHC molecules.

The TCR is composed of two core glycoprotein subunits (Figure 24-31), each of which is encoded by a somatically rearranged gene. The receptor is usually composed of an α and a β subunit, but certain TCRs are alternatively composed of a γ and a δ subunit. The structure of these subunits is similar to that of the F(ab) portion of

an immunoglobulin: at the N-terminal end is a variable region, followed by a constant region and a transmembrane segment. The cytoplasmic tails of the TCR subunits are short and do not directly interact with cytoplasmic signal transduction molecules. Instead, the TCR associates with the CD3 complex, a set of membrane glycoproteins composed of γ, δ, ε, and ζ chains. The structure of this complex has been determined by cryoelectron microscopy (Figure 24-31b). The extracellular domains of the CD3 subunits are similar to immunoglobulin domains, and the cytoplasmic domain in each contains an ITAM (immunoreceptor tyrosine-based activation motif), which recruits adapter proteins upon phosphorylation of its tyrosine residues. The ζ chain is integrated into the CD3-TCR complex as a disulfide-bonded homodimer, and each ζ chain contains three ITAMs (see Figure 24-33).

FIGURE 24-31 Structure of the T-cell receptor and its co-receptors. (a) The antigen-specific T-cell receptor (TCR) is composed of two chains, the α and β subunits, which are produced by V-J and V-D-J recombination, respectively (see Figure 24-32). The α and β subunits must associate with the CD3 complex (not

shown; see panel b and Figure 24-33) to allow the transduction of signals. The formation of a full TCRαβ–CD3 complex is required for surface expression. The TCR further associates with a co-receptor, CD8 (light blue) or CD4 (light green), which allows interaction with conserved features of class I MHC or class II MHC molecules, respectively, on antigen-presenting cells. (b) Structure of the extracellular portion of the TCR-CD3 complex as determined by cryoelectron microscopy. The subunits of the CD3 complex are color-coded. The extracellular portions of the T-cell receptor α(TCRα) and β(TCRβ) subunits as well as those of CD3γ,δ, and ε all possess the basic fold of immunoglobulin domains. The cytoplasmic portions of the CD3 complex subunits were not resolved by cryoelectron microscopy and are therefore absent from the figure. Unlike the CD3γ, δ, and ε subunits, the CD3ζ chain has a minimal extracellular domain. The intracellular portions of the CD3 complex contain the immunoreceptor tyrosine-based activation motifs (ITAMs) essential for signal transduction via the TCR-CD3 complex.

[Part (b) republished with permission from Nature Publishing Group, from E. L. Reinherz, 2019, "The Structure of a T-Cell Mechanosensor," *Nature* **573**(7775):502–504; permission conveyed through Copyright Clearance Center, Inc.]

TCR Genes Are Rearranged in a Manner Similar to Immunoglobulin Genes

Virtually all antigen-specific receptors generated by somatic recombination contain a subunit that is the product of V-D-J recombination (e.g., Ig heavy chain; TCR β chain) and another that is the product of V-J recombination (e.g., Ig light chain; TCR α chain). The mechanism of V-D-J and V-J recombination for TCRs is essentially identical to that described for immunoglobulin genes

and requires all the component proteins composing the nonhomologous end-joining machinery: RAG1, RAG2, Ku70, Ku80, the catalytic subunit of DNA-dependent protein kinase, XRCC4, DNA ligase IV, and Artemis. Similarly *r*ecombination *s*ignal *s*equences (RSSs) are required (Figure 24-32).

FIGURE 24-32 Organization and recombination of TCR loci. The organization of TCR loci is in principle similar to that of immunoglobulin loci (see Figure 24-15). *Left:* The TCR β-chain locus includes a cluster of V segments, a cluster of D segments, and several J segments,

downstream of which are two constant regions. The arrangement of the recombination signals is such that not only is D-J joining allowed, but also D-D joining followed by joining to a V segment. Direct V-J joining in the TCR β locus is not observed even though the arrangement of the recombination signal sequences would be consistent with such a possibility. *Right:* The TCR α-chain locus is composed of a cluster of V segments and a large number of J segments. SS = exon encoding signal sequence; Enh = enhancer.

A number of noteworthy features characterize the organization and rearrangement of the TCR loci. First, the organization of the RSSs is such that D-to-D rearrangements are allowed, unlike the case for Ig. Second, terminal deoxynucleotidyltransferase (TdT) is active at the time the TCR genes are rearranged, and therefore additional nucleotides, termed *N nucleotides*, can be present at the V-D and D-J junctions in all rearranged TCR genes. Third, in humans and mice, the TCR δ locus is embedded within the TCR α locus. This organization results in complete excision of the interposed δ locus when TCR α rearrangement occurs, so a choice of the TCR α locus for rearrangement precludes use of the δ locus, which is lost by deletion. T cells that express the αβ receptor and those that express the γδ receptor are considered separate lineages with distinct functions. Among the T-cell γδ receptors are some capable of recognizing the CD1 molecule, which as we learned is specialized for the presentation of lipid antigens. The γδ T cells are programmed to home to distinct anatomic sites (e.g., the epithelium lining, the genital tract, or the skin) and probably play a role in host defense against pathogens commonly found at these sites. They may also have anti-tumor activity.

Deficiencies in the key components of the recombination apparatus, such as the RAG recombinases, preclude rearrangement of TCR genes. As we have seen for B cells, development of lymphocytes is strictly dependent on the rearrangement of the antigen-receptor genes. A deficiency in either RAG1 or RAG2 thus prevents both B-cell and T-cell development. Mice with homozygous RAG gene knockouts are frequently used to assess the roles of B and T cells in physiological and pathophysiological processes.

Many of the Variable Residues of TCRs Are Encoded in the Junctions Between V, D, and J Gene Segments

The diversity created by somatic recombination of TCR genes is estimated to exceed 10^{10} unique receptors. Combinatorial use of different V, D, and J gene segments makes an important contribution to this diversity, as do the mechanisms of junctional imprecision and N-nucleotide addition already discussed for immunoglobulin gene rearrangements. The net result is a degree of variability in the V regions that at least matches that of the immunoglobulins (see Figure 24-13). Indeed, each of the TCR's variable regions includes three hypervariable regions (CDRs), equivalent to those in the BCR. Unlike immunoglobulin genes, however, the TCR genes do not undergo somatic hypermutation. Therefore, TCRs exhibit nothing equivalent to the affinity

maturation of antibodies during the course of an immune response, nor is there the option of class-switch recombination or the use of alternative polyadenylation sites to create soluble and membrane-bound versions of the receptors.

The crystal structures of a number of TCRs bound to class I MHC–peptide or class II MHC–peptide complexes have been determined. These structures show variation in how the TCR docks with the MHC-peptide complex, but the most extensive contacts in the somatically diverse CDR3 region are made with the central peptide-containing portion of the complex, with the germ line–encoded CDR1 and CDR2 contacting the α helices of the MHC molecules. Many of the TCRs for which a structure has been solved dock diagonally across the peptide-binding portion of the MHC-peptide complex. As a result, the TCR makes extensive contacts with the peptide as well as with the α helices of the MHC molecule to which it binds. The positions at which allelic MHC molecules differ from one another are frequently those residues that directly contact the TCR, thus precluding tight binding of unrelated allelic MHC products.

Amino acid differences that distinguish one MHC allele from another also affect the architecture of the peptide-binding cleft. Even if the MHC residues that interact directly with the TCR were shared by two allelic MHC molecules, their peptide-binding specificity would probably differ because of amino acid differences in the peptide-binding cleft. Consequently, the TCR contact residues provided by bound peptide, which are essential for stable

interaction with a TCR, would be absent from the wrong MHC-peptide combination. A productive interaction with the TCR would then be unlikely to occur. As mentioned earlier, these molecular features are the underpinnings of MHC restriction.

Signaling via Antigen-Specific Receptors Triggers Proliferation and Differentiation of T and B Cells

The immune responses mediated by T cells and B cells are initiated once TCRs or BCRs bind their respective ligands and are thus activated. The ligands for TCRs are MHC-peptide complexes expressed on the surfaces of APCs. The ligands for BCRs are antigens that bind to the receptors without the need for MHC intervention or a presenting cell. TCR and BCR activation by their antigens is similar to the activation of signaling receptors like tyrosine kinase receptors that we have considered previously (see Chapter 16). In all cases, multiple phosphotyrosine signal transduction cascades are engaged. Several integral membrane proteins, as well as soluble cytosolic enzymes, participate in TCR and BCR signaling. In some cases, these membrane-associated proteins can be thought of as auxiliary subunits of the receptors. Examples of how such auxiliary proteins participate in signaling are shown in Figure 24-33. The cytosolic portions of the antigen-specific receptors do not protrude much beyond the cytosolic leaflet of the

plasma membrane, and are incapable of recruiting downstream signaling molecules. Instead, the antigen-specific receptors associate with auxiliary subunits that contain ITAMs. Engagement of the antigen-specific receptors by ligand initiates a series of receptor-proximal events: kinase activation, phosphorylation of one or two tyrosine residues in the ITAM sequence, and subsequent binding to these phosphotyrosines of SH2 domains of adapter proteins that serve as scaffolds for recruitment of other downstream signaling molecules.

FIGURE 24-33 Signal transduction from the T-cell receptor (TCR) and B-cell receptor (BCR). The signal transduction pathways used by the antigen-specific receptors of T cells (*left*) and B cells (*right*) are conceptually similar. The initial stages are depicted in this figure; downstream signaling events lead to changes in gene expression that result in proliferation and differentiation of the antigen-stimulated lymphocytes. See text for further discussion.

One major downstream signal transduction pathway is outlined in Figure 24-33. Engagement of the antigen-specific receptors by ligand activates Src-family cytosolic tyrosine kinases (e.g., Lck in helper T cells; Lyn and Fyn in B cells; Figure 24-33, step **1**); these kinases are found in close proximity to or physically associated with the antigen-specific receptors. The active kinases phosphorylate tyrosine residues in the ITAMs (step **2**). In their phosphorylated forms, the ITAMs bind to SH2 domains of non-Src-family tyrosine kinases (ZAP-70 in T cells, Syk in B cells), leading to activation of these kinases (step **3**). The ITAMs bind other adapter proteins, which are activated by the non-Src-family tyrosine kinases. As with

other phosphotyrosine-triggered signaling pathways (see Chapter 16) this leads to activation of phosphoinositide-specific phospholipase Cγ and several PI-3 kinases. Subsequent downstream events parallel those described in Chapter 16 for signaling from receptor tyrosine kinases. Antigen-specific receptors on B and T cells are perhaps best characterized as modular receptor tyrosine kinases, with the ligand recognition units and kinase domains carried by separate molecules. Ultimately, signaling via these T cell and B cell antigen-specific receptors initiates transcription programs that determine the fate of the activated lymphocyte: proliferation and differentiation.

T cells depend critically on the cytokine interleukin 2 (IL-2) for clonal expansion. Following antigen stimulation of a T cell, one of the first genes to be turned on is that for IL-2 (see Figure 16-19). The T cell responds to its own initial burst of IL-2 and proceeds to make more IL-2, an example of autocrine stimulation and part of a positive feedback loop. An important transcription factor required for the induction of IL-2 synthesis is the NF-AT protein (*n*uclear *f*actor of *a*ctivated *T* cells). This protein is sequestered in the cytoplasm in phosphorylated form and cannot enter the nucleus unless it is de-phosphorylated first. The phosphatase responsible is calcineurin, a Ca^{2+}-activated enzyme. The initial rise in cytosolic Ca^{2+} leading to activation of calcineurin results from mobilization of ER-resident Ca^{2+} stores triggered by hydrolysis of $PI(4,5)P_2$ and the concomitant generation of IP_3 (see Figure 15-28, steps **2** – **4**).

The immunosuppressant drug cyclosporine inhibits calcineurin activity through formation of a cyclosporine-cyclophilin complex, which binds and inhibits calcineurin. If de-phosphorylation of NF-AT is suppressed, NF-AT cannot enter the nucleus and induce transcription of the *IL-2* gene. This precludes clonal expansion of antigen-stimulated T cells and so leads to immunosuppression, arguably the single most important intervention that contributes to the success of organ transplantation involving unrelated donors and recipients (individuals who are genetically different and therefore express different MHC products), referred to as *allogeneic* tissue transplantation. Although the success of transplantation varies with the organ used, the availability of strong immunosuppressants such as cyclosporine has expanded the possibilities of clinical transplantation enormously. ■

T Cells Capable of Recognizing MHC Molecules Develop Through a Process of Positive and Negative Selection

Rearrangement of the gene segments that are assembled to encode a functional T-cell receptor is a stochastic event, completed on the part of the T cell without any prior knowledge of the MHC molecules with which its receptors must ultimately interact. As in somatic recombination of Ig heavy-chain loci in B cells, the first gene segments to be rearranged in the TCR β chain are the D and J

elements; a V segment is then joined to the newly recombined DJ (see Figure 24-32). At this stage of T-cell development, productive rearrangement allows the synthesis of the TCR β chain, which is incorporated into the pre-TCR through association with a surrogate α subunit termed *pre-Tα*. This dimeric pre-TCR fulfills a function strictly analogous to that of the pre-BCR in B-cell development: it tells the T cell that it has successfully completed a productive β chain rearrangement, with no need for further rearrangements in the β chain gene on the homologous chromosome. The pre-TCR allows clonal expansion of the pre-T cells that successfully underwent TCR β chain rearrangement, and it imposes allelic exclusion to ensure that, as a rule, a single functional TCR β subunit is generated for a given T cell and its descendants. RAG expression subsides until the expansion phase of the pre-T cells is complete, after which it is re-initiated to allow rearrangement of the TCR α locus, ultimately leading to the generation of T cells with a fully assembled TCR containing a rearranged α and β subunit. Figure 24-34 illustrates the analogous steps in the development of T and B cells.

FIGURE 24-34 Comparison of T-cell and B-cell development. Cell fate decisions are executed by receptors containing either the newly rearranged μ chain (pre-BCR) or the newly rearranged β chain (pre-TCR). The pre-BCRs and pre-TCRs serve similar functions: signaling clonal expansion of cells that have successfully undergone rearrangement and allelic exclusion. This phase of lymphocyte development does not require antigen recognition. Both the pre-BCR and pre-TCR include subunits unique to each receptor type and absent from the antigen-specific receptors found on mature lymphocytes: VpreB and λ5 (orange, green) for the pre-BCR; pre-T α (blue) for the pre-TCR. Upon completion of the expansion phase, expression of the gene encoding the remaining subunit of the antigen-specific receptor begins: Ig light chain (light blue) for the BCR; TCR α chain (light red) for the TCR. Lymphocyte development and differentiation occur at distinct anatomic sites, and only fully assembled antigen-specific receptors (BCR, TCR) recognize antigen. Mature lymphocytes are strictly dependent on antigen recognition for their activation.

How is the emerging repertoire of T cells, with its diverse set of pre-TCRs, further sorted so that the only surviving T cells are ones

whose receptors have a productive interaction with self-MHC–peptide complexes? The random nature of the gene rearrangement process and the enormous variability engendered as a consequence produces a large and diverse set of TCRs. Yet the vast majority of this set of TCRs cannot interact productively with the host MHC products and are therefore useless. Thymocytes bearing useless receptors are not exported to the periphery: they wither on the vine and die. The immune system has developed selection processes to eliminate T cells that make TCRs incapable of a productive interaction with peptide complexes to the organism's own MHC (self MHC). Selection in the thymus also removes T cells with TCRs that strongly interact with self-MHC–self-peptide complexes, because such T cells may be self-reactive, damaging normal healthy tissue (autoimmunity). T cells whose TCRs recognize peptide-MHC complexes in the thymus with an affinity that falls between these two extremes receive survival signals and are positively selected. Some may by chance have the ability to bind strongly to an MHC protein complexed to a peptide derived from a foreign protein. Recall that antigen processing and presentation are constitutive processes, so that in the thymus, all self-MHC molecules are necessarily occupied with peptides derived from self proteins. These combinations of self peptides complexed to class I and class II MHC molecules constitute the substrate used by the set of newly generated T-cell receptors to determine what is self and ought to be ignored.

The heterogeneity of peptide-MHC complexes presented by different cells in the thymus to T cells undergoing selection makes it

highly probable that the T-cell receptor interprets signals not only by the strength and duration of the interaction with a particular peptide-MHC complex, but also in additive fashion, meaning the summation of the binding energies of the different MHC–self-peptide combinations it encounters. These help determine the outcome of the self–nonself selection. This process is called the *avidity model of T-cell selection*.

Newly made T cells are killed by apoptosis only if the appropriate self antigen is represented adequately in the thymus in the form of MHC-peptide complexes. How does the immune system ensure that T cells generated in the thymus learn to ignore self antigens that are not normally expressed at that location? Proteins that are expressed in tissue-specific fashion or after the development of the thymus, such as insulin in the β cells of the pancreas or the components of the myelin sheath in the nervous system, fit this category. A factor called *AIRE (a*uto*i*mmune *re*gulator) allows expression of such tissue-specific antigens in a subset of epithelial cells in the thymus. How AIRE accomplishes this is not known, but it is widely suspected that AIRE directly regulates the transcription of the relevant genes in the thymus and at select sites in secondary lymphoid organs. Defects in AIRE lead to a failure to express these tissue-specific antigens in the thymus. In individuals who do not express AIRE, developing T cells fail to receive the full set of instructions in the thymus that lead to the elimination of potentially self-reactive T cells. As a consequence, these individuals show a bewildering array

of autoimmune responses, causing widespread tissue damage and disease.

T Cells Commit to the CD4 or CD8 Lineage in the Thymus

TCR gene rearrangement coincides with the acquisition of co-receptors. A key intermediate in T-cell development is a thymocyte that expresses both of the TCR co-receptors, CD4 and CD8, as well as a functional TCR-CD3 complex. These cells, called *double-positive* ($CD4CD8^+$) *cells*, are found only as developmental intermediates in the thymus. As the T cells mature, they lose either CD4 or CD8 to become single-positive cells. The choice of which co-receptor (CD4 or CD8) to express determines whether a T cell will recognize class I or class II MHC molecules. The question of how a $CD4CD8^+$ cell is instructed to become a CD8 (class I MHC-restricted) T cell or a CD4 (class II MHC-restricted) T cell is not entirely settled, but we know that the transcription factors ThPOK and Runx3 play fundamental roles. ThPOK and Runx3 are regulated by TCR signaling. Cells that transiently express ThPOK will commit to the CD4 lineage and repress Runx3 expression. On the other hand, if ThPOK expression is not induced, Runx3 expression is high, and cells commit to the CD8 lineage. In mice, a loss-of-function mutation in the *ThPOK* gene abrogates CD4 T-cell development, and all thymocytes become CD8-expressing T cells.

Another type of CD4 T cell also develops in the thymus, named *natural* (or *thymically derived*) *regulatory T cells (Treg)*. Their function differs from that of CD4 helper T cells, as will be described below. The thymus also gives rise to other less numerous types of T cells, such as invariant natural killer T cells (iNKT) that express the NK cell marker NK1.1 and are selected based on their ability to bind the nonclassic MHC molecule CD1, which presents lipid antigens. Also generated are intraepithelial lymphocytes that will colonize the mucosal surfaces of the intestine. After the final stages of maturation, T cells of all types are exported to the peripheral lymphoid organs.

T Cells Require Two Types of Signals for Full Activation

All T cells require a signal via their TCR for activation, but that signal is not sufficient: the T cell also needs co-stimulatory signals that are present on an antigen-presenting cell. To perceive these co-stimulatory signals, T cells carry on their surface several additional receptors, of which the CD28 molecule is the best known example. It is these regulatory signals that are the basis of cancer immunotherapies using monoclonal antibodies that target certain of these signaling proteins: CTLA4, PD-1, and PD-L1. These therapies are discussed in Section 24.6.

The CD28 protein on a T cell interacts with CD80 and CD86, two surface glycoproteins on the professional APC with which the T cell interacts. Expression of CD80 and CD86 increases when these APCs have themselves received the proper stimulatory signals, for example, by engagement of their Toll-like receptors (TLRs). The signals delivered to T cells via CD28 synergize with signals that emanate from the TCR when bound to its cognate self-MHC–peptide antigen complex, all of which are required for full T-cell activation (Figure 24-35, steps **1**–**3**).

FIGURE 24-35 Signals involved in T-cell activation and its termination. The two-signal model of full T-cell activation: signal 1 is recognition of an MHC-peptide complex by the T-cell receptor (step 1), and signal 2 is recognition by CD28 of co-stimulatory molecules (CD80, CD86) on the surface of an antigen-presenting cell (step 2). Full activation, in turn, leads to increased expression of CTLA4 on the surface of T cells (step 3). CTLA4 binds CD80 and CD86, leading to inhibition of the T-cell response (step 4). Because the affinity of CTLA4 for CD80 and CD86 is greater than that of CD28, T-cell activation is eventually terminated. Note that after signal 1, if co-stimulation is not provided, the newly engaged T cell becomes unresponsive (anergic).

T cells, once activated, also express receptors that provide an attenuating or inhibitory signal upon recognition of these very same co-stimulatory molecules, providing negative feedback regulation. The CTLA4 protein, whose expression in T cells is induced only upon activation, competes with CD28 for binding of CD80 and CD86. Because the affinity of CTLA4 for the CD80 and C86 proteins is higher than that of CD28, the inhibitory signals provided through

CTLA4 will ultimately overwhelm the stimulatory signals coming via CD28. Co-stimulatory molecules can thus be stimulatory or — as was discovered later without adjusting the nomenclature — inhibitory, and they therefore provide an important means of controlling the activation status and duration of a T-cell response.

Cytotoxic T Cells Carry the CD8 Co-Receptor and Are Specialized for Killing

As we have seen, cytotoxic T cells (CTLs) generally express on their surfaces the TCR co-receptor glycoprotein called *CD8*. These $CD8^+$ T cells kill target cells that display their cognate class I MHC–peptide combinations and do so with exquisite sensitivity: a single MHC-peptide complex suffices to allow a properly activated CTL to kill the target cell that bears it.

The mechanism of killing by CTLs involves two classes of proteins that act synergistically: perforins and granzymes (Figure 24-36). Perforins exhibit homology to the terminal components of the complement cascade composing the membrane attack complex (see Figure 24-5). Like the attack complex, perforins attach to a membrane and form pores up to 20 nm across within the membrane. The pores cause electrolytes and other small solutes to leak from the cell, contributing to cell death. Granzymes are

delivered to and are presumed to enter the target cell, probably via the pores generated by perforin. Granzymes are serine proteases that activate caspases and so propel the target cell on a path of programmed cell death (apoptosis; see Chapter 22). Perforins and granzymes are packaged into cytotoxic granules, which are stored inside the cytotoxic T cell. Upon binding of the T-cell receptor to its cognate class I MHC–antigen complex, signal transduction from the TCR leads to release of the cytotoxic granules and their contents into the extracellular space that is formed between the cytotoxic T cell and the target cell, called the *synaptic cleft*. How the T cell avoids being killed upon release of granzymes and perforins into the synapse is unknown. Natural killer cells also exert cytotoxic activity and likewise rely on perforins and granzymes to kill their targets (see Figure 24-6).

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

FIGURE 24-36 Perforin- and granzyme-mediated cell killing by cytotoxic T cells. Upon recognition of a target cell (step 1), a cytotoxic T cell forms a tight antigen-specific contact with the target cell. Tight contact results in the formation of a synaptic cleft, into which the contents of cytotoxic granules, including perforins and granzymes, are released (step 2). Perforins form pores in the membranes onto which they adsorb, and granzymes are serine proteases that enter through the perforin pores (step 3). Perforins are believed to act not only at the surface of the target cell, but also at the surface of its endosomal compartments after the perforin molecules have been internalized from the cell surface (step 4). Once in the cytoplasm, the granzymes activate caspases, which initiate programmed cell death (step 5).

T Cells Secrete an Array of Cytokines That Provide Signals to Other Immune-System Cells

Many lymphocytes and other cells in lymphoid tissues produce cytokines. These small secreted proteins control lymphocyte activity by binding to specific cytokine receptors on the surface of a lymphocyte and initiating a transcriptional program that allows the lymphocyte to either proliferate or differentiate into an effector cell ready to exert cytotoxic (cytotoxic T cells), helper (helper T cells), or antibody-secreting activity (B cells). Cytokines that are produced by or act primarily on leukocytes are called **interleukins**. More than 35 interleukins have been recognized and molecularly characterized. Interleukin receptors share structural similarity with each other and with receptors for erythropoietin; those interleukins whose structures are most closely related can be recognized by their cognate receptors. The interleukin-2 receptor (Figure 16-19b) is particularly well characterized. Interleukin 2 (IL-2), a T-cell growth factor, is one of the first cytokines produced when T cells are stimulated. IL-2 acts as an autocrine (self-acting) and paracrine (acting on neighboring cells) growth factor and drives clonal expansion of activated T cells.

Interleukin 4 (IL-4), which is produced by helper T cells, induces activated B cells to proliferate and to undergo class-switch recombination and somatic hypermutation. Interleukin 7 (IL-7), produced by stromal cells in the bone marrow, is essential for development of T and B cells. Both IL-7 and IL-15 play a role in the maintenance of *memory cells*, which are antigen-experienced T cells that may be called upon when re-exposure to antigen occurs; these

memory cells then rapidly proliferate and deal with the reinvading pathogens. The receptors for IL-2, IL-4, IL-7, and IL-15 all rely on a common subunit for signal transduction, the common γ chain (γ_c), with α (IL-2, IL-15) and β subunits (IL-2, IL-4, IL-7, IL-15) providing ligand specificity (Figure 16-19b). Genetic defects in the γ_c result in nearly complete failure of lymphocyte development, illustrating the importance of these cytokines (and their receptors) not only during the effector phase of an immune response, but also in the course of lymphocyte development, where IL-7 in particular plays a key role. By knocking out the gene that encodes γ_c, immunodeficient mice can be generated that accept human tissues and tumors as grafts. Such mice have become very useful models to study tumor immunology and to create a setting in which a partial human immune system can be installed in mice, for example, to study HIV, which does not infect mouse lymphocytes.

The mechanism of signal transduction by cytokine receptors through the JAK/STAT pathway is described in Chapter 16 (reviewed in Figure 16-19a). Among the many genes under the control of interleukins and the STAT pathway are those that encode suppressors of cytokine signaling, or SOCS proteins. These proteins, which are themselves induced by cytokines, bind to the activated form of JAKs and target them for proteasomal degradation (see Figure 16-21b).

Helper T Cells Are Divided into Distinct Subsets Based on Their Cytokine Production and Expression of Surface Markers

CD4-expressing T cells are helper T cells that provide assistance to B cells and guide their proliferation and differentiation into plasma cells. This function requires both the production and secretion of cytokines such as IL-4 as well as direct contact between the helper T cell and the B cell to which it provides help.

A second class of helper T cell has as its major function secreting the cytokines that contribute to the establishment of an inflammatory environment. Multiple subtypes of such inflammatory T cells are categorized based on the spectrum of different cytokines they produce and their respective roles in regulating immune responses. Whereas all activated T cells can produce IL-2, other cytokines are produced only by particular helper T-cell subsets.

Helper T cells classified as T_H1 cells secrete interferon γ and tumor necrosis factor (TNF), which can activate macrophages and stimulate an inflammatory response. Referred to also as *inflammatory T cells*, T_H1 cells nonetheless play an important role in antibody production, notably facilitating the production of complement-fixing antibodies such as IgG1 and IgG3. T_H2 cells

secrete IL-4 and IL-10, and through production of IL-4, play an important role in B-cell responses that involve class switching to the IgG1 and IgE isotypes (see Section 24.3). Recall that in B cells, the induction of activation-induced deaminase (AID) prepares the B cell for class-switch recombination and somatic hypermutation. This induction is a consequence of the precise mixture of cytokines produced by helper T cells and the binding of CD40, a surface membrane protein on the activated T cell, to a protein on the B-cell surface, called *CD40 ligand* or *CD40L*.

Conventional helper T cells can also differentiate into T_H17 cells, which produce IL-17, and into *induced regulatory T cells* (induced Tregs, distinct from the natural Tregs generated in the thymus). Both types of Treg cells attenuate immune responses by exerting a suppressive effect on other types of T cells. Natural Tregs restrain the activity of potentially self-reactive T cells and are important in maintaining peripheral tolerance (the absence of an immune response to self antigens), whereas induced Tregs are believed to regulate excessively strong immune responses against foreign antigens. T_H17 cells are important in defense against bacteria (extracellular bacteria in particular) and also play a pathogenic role in autoimmune diseases.

Innate Lymphoid Cells Regulate Inflammation and the Overall Immune

Response

The immune response against a pathogen exerts a selective pressure that allows the emergence of pathogen variants no longer recognized by antibodies or T cells. Many viruses with comparatively small genomes, such as the virus that causes influenza or human immunodeficiency virus, replicate by means of error-prone polymerases that generate mutant descendants with amino acid substitutions, some of which escape immune recognition because the proper epitope is no longer expressed as a consequence of such mutations. Viruses with large genomes such as herpesviruses use other means of immune escape, for example, through down-regulation of Class I MHC products. This renders the infected cell refractory to killing by CD8 T cells. A similar situation applies to many cancerous cells, which often show starkly reduced expression of Class I MHC products. Natural killer (NK) cells can sense the absence of Class I MHC products because NK cells express receptors that recognize Class I MHC products and shut off NK cell function. A lack of Class I MHC products on the surface of a virus-infected cell or on a tumor cell relieves the inhibition mediated by such receptors and allows the NK cell to kill the target. Because of this, the combined action of CD8 T cells and NK cells affords a level of protection against virus-infected and tumor cells that is more effective than either cell type can confer on its own.

Although NK cells were discovered several decades ago, they are now referred to as a member of the group of *innate lymphoid cells* or *ILCs*. Such cells resemble conventional lymphocytes in many of their functional properties such as the types of cytokine they can produce, but they do not make use of gene rearrangements to create the receptors characteristic of the cells of the adaptive immune system: the B and T cells. ILCs are important in regulating inflammation and in regulatory control of the immune response more generally. They are poised to rapidly secrete cytokines when activated and their preferred location at mucosal sites suggests a role in the control of various infections. The group 1 ILC lineage comprises ILCs such as NK cells that produce type 1 cytokines, notably interferon-γ and TNF. ILC2s express interleukin-5 (IL-5) and IL-13, not unlike conventional T_H2 CD4 T cells. ILC2s, together with T_H2 CD4 T cells, protect against helminth (parasitic worms) infection. ILC3s were first defined as intestinal lymphoid cells that express the NK cell–activating receptor NKp46 but are otherwise quite distinct from NK cells (ILC1s). ILC3s express IL-17A and IL-22. Lymphoid tissue-inducer (LTi) cells are an ILC subset that appears to be closely related to ILC3s, but their exact relationship remains controversial. Together, LTi cells and ILC3s have been classified as group 3 ILCs.

Leukocytes Move in Response to Chemotactic Cues Provided by

Chemokines

Interleukins tell lymphocytes what to do by eliciting a transcriptional program that allows lymphocytes to acquire specialized effector functions. Chemokines, on the other hand, tell leukocytes where to go. Many cells emit chemotactic cues in the form of chemokines. When tissue damage occurs, resident fibroblasts produce a chemokine, IL-8, that attracts neutrophils to the site of damage. The regulation of lymphocyte traffic within lymph nodes is essential for dendritic cells to attract T cells and for T cells and B cells to meet. These trafficking steps are all controlled by chemokines.

There are approximately 40 distinct chemokines and more than a dozen chemokine receptors. One chemokine may bind to more than one receptor, and a single receptor can bind several different chemokines. This flexibility creates the possibility of generating a combinatorial code of chemotactic cues of great complexity. This code is used to guide the navigation of leukocytes from where they are generated, in the bone marrow, into the bloodstream for transport to their target destination.

Some chemokines direct lymphocytes to leave the circulation and take up residence in lymphoid organs. These migrations contribute to the population of lymphoid organs with the required sets of lymphocytes. Because these movements occur as part of normal lymphoid development, such chemokines are referred to as

homeostatic chemokines. Those chemokines that serve the purpose of recruiting leukocytes to sites of inflammation and tissue damage are referred to as *inflammatory chemokines*.

Chemokine receptors are G protein–coupled receptors that function as an essential component of the regulation of cell adhesion and cell migration. Leukocytes that travel through blood vessels do so at high speed and are exposed to high hydrodynamic shear forces. For a leukocyte to traverse the endothelium and take up residence in a lymph node or seek out a site of infection in tissue, it must first slow down, a process that requires interactions of glycoprotein surface receptors called *selectins* with their ligands on the surfaces of leukocytes, which are mostly carbohydrate in nature. If chemokines are adsorbed to the extracellular matrix and if the leukocyte possesses a receptor for those chemokines, activation of its chemokine receptor elicits a signal that allows integrins carried by the leukocyte to undergo a conformational change. This change results in an increase in the affinity of the integrin for its ligand and causes firm arrest of the leukocyte. The leukocyte may now exit the blood vessel by a process known as *extravasation* (see Figure 20-40).

KEY CONCEPTS OF SECTION 24.5

T Cells, T-Cell Receptors, and T-Cell Development

- The antigen-specific T-cell receptors are dimeric proteins consisting of α and β subunits or γ and δ subunits. T cells occur in at least two major classes defined by their expression of the glycoprotein co-receptors CD4 and CD8 (see Figure 24-31).

- Cells that use class I MHC molecules as the molecular guideposts for antigen recognition (restriction elements, in immunological parlance) carry CD8; those that use class II MHC molecules carry CD4. These classes of T cells are functionally distinct: CD8 T cells are cytotoxic T cells; CD4 T cells provide help to B cells and are an important source of cytokines.
- Genes encoding the TCR subunits are generated by somatic recombination of V and J segments (α chain) and of V, D, and J segments (β chain); their rearrangement obeys the same rules as does rearrangement of Ig genes in B cells (see Figure 24-32). Rearrangement of TCR genes occurs when the lymphocytes are present in the thymus and only in those cells destined to become T lymphocytes.
- A complete T-cell receptor includes not only the α and β subunits responsible for antigen and MHC recognition, but also the accessory subunits referred to as the *CD3 complex*, which is required for signal transduction. Each subunit of the CD3 complex carries in its cytoplasmic tail one or three ITAM domains; when phosphorylated, these ITAMs recruit adapter proteins involved in signal transduction (see Figure 24-33).
- In the course of T-cell development, the TCR β locus is rearranged first. If that locus encodes a functional β subunit, it is incorporated with the pre-Tα chain into a pre-TCR (see Figure 24-34). Like the pre-BCR, the pre-TCR mediates allelic exclusion, that is, the expression of a functionally rearranged T-cell receptor encoded by only one of the two alleles and proliferation of those cells that successfully underwent TCRβ rearrangement.
- Developing T cells that fail to recognize self-MHC molecules die for lack of survival signals. T cells that interact too strongly with self-peptide–self-MHC complexes encountered during development are instructed to die (negative selection); those that have intermediate affinity for self-peptide–self-MHC complexes are allowed to mature (positive selection) and are exported from the thymus to the periphery.
- Innate lymphoid cells (ILCs) share properties with lymphocytes, notably the types of cytokines they release, without reliance on antigen-specific receptors, unlike T lymphocytes.
- T cells are instructed where to go (cell migration) through chemotactic signals in the form of chemokines. Receptors for chemokines are G protein–coupled receptors that show some promiscuity in terms of their binding of chemokines. The complexity of chemokine–chemokine receptor binding allows precise regulation of leukocyte traffic, both within lymphoid organs and in the periphery.

24.6 Collaboration of Immune-System Cells in the Adaptive Response

An effective adaptive immune response requires the presence of B cells, T cells, and antigen presenting cells (APCs). For B cells to execute class-switch recombination and somatic hypermutation — prerequisites for production of high-affinity antibodies — they require help from activated T cells. These T cells, in turn, can be activated only by professional APCs such as dendritic cells. Dendritic cells sense the presence of pathogens through Toll-like receptors and other pattern-recognition receptors, such as the cell-surface mannose-binding protein and other related lectins that can recognize polysaccharides and carbohydrate determinants. The interplay between components of the innate and adaptive immune systems is therefore a very important aspect of adaptive immunity. This layered, interwoven nature of innate and adaptive immunity ensures a rapid early response of immediate protective value and primes the adaptive immune system for a specific response to any persisting pathogen. In this section, we describe how these various elements are activated and how the relevant cell types interact.

Toll-Like Receptors Perceive a Variety of Pathogen-Derived Macromolecular

Patterns

An important part of the innate immune system is its ability to immediately detect the presence of a microbial invader and respond to it. This response includes direct elimination of the invader, but it also prepares the mammalian host for a proper adaptive immune response, particularly through activation of professional APCs. These APCs are positioned throughout the epithelia (airways, gastrointestinal tract, genital tract), where contact with pathogens is most likely to occur. In the skin, a network of dendritic cells called *Langerhans cells* makes it virtually impossible for a pathogen that breaches this barrier to avoid contact with these professional APCs. Dendritic cells and other professional APCs detect the presence of bacteria and viruses through members of the Toll-like receptor (TLR) family. These proteins are named after the *Drosophila* protein Toll because of the structural and functional homology between them. *Drosophila* Toll was discovered because of its important role in dorsal/ventral patterning in the fruit fly, but related receptors are now recognized as capable of triggering an innate immune response in insects as well as in vertebrates.

TLR Structure

Toll itself and all TLRs possess a sickle-shaped extracellular domain, composed of *leucine-rich repeats*, that is involved in ligand recognition. The cytoplasmic portion of a TLR contains a domain

responsible for the recruitment of adapter proteins to enable signal transduction. The signaling pathways engaged by TLRs have many of the same components (and outcomes) as those used by receptors for the cytokine IL-1 (Figure 24-37; see also Figure 16-31).

FIGURE 24-37 Toll-like receptor activation. The extracellular portions of TLRs recognize ligands of diverse chemical nature (nucleic acids, lipopolysaccharides). The cytoplasmic portions of the TLRs, called *TIR* (BToll/IL-1β receptor homology) domains, associate with the adapter protein MyD88, present in six copies per complex, and recruit two types of kinases, both members of the IRAK family. These complex interactions are maintained by TIR

domains and death domains (DD) as shown in the figure. The assembled complex on the cytoplasmic side is referred to as the *myddosome*. As depicted in Figure 16-31, among the proteins bound to IRAK2 is TRAF6, an E3 ubiquitin ligase. Because of extensive TRAF6-TRAF6 interactions, hundreds of copies of this TLR complex become cross-linked together, forming a giant signalsome in the plasma membrane.

The *Drosophila* Toll protein interacts with its ligand, Spaetzle, itself the product of a proteolytic conversion initiated by components of the cell walls of fungi that prey on *Drosophila*. In the fly, activation of Toll unleashes a signaling cascade that ultimately controls the transcription of genes that encode antimicrobial peptides. The activated receptor at the cell surface communicates with the transcriptional apparatus by means of a series of adapter proteins that activate downstream kinases interposed between Toll, the TLRs, and the transcription factors that are activated by them. A key step is the ubiquitin-dependent proteasomal degradation of the Cactus protein. Its removal allows the protein Dif to enter the nucleus and initiate transcription. This pathway is highly homologous in its operation and structural composition to the NF-κB pathway in mammals (see Figure 16-30).

Diversity of TLRs

There are approximately a dozen mammalian TLRs that can be activated by various microbial products and are expressed by a variety of cell types; TLR function is crucial for the activation of dendritic cells and macrophages. Neutrophils also express TLRs. The microbial products recognized by TLRs include macromolecules found in the cell envelopes of bacteria, such as lipopolysaccharides, flagellins (subunits of bacterial flagella), and bacterial lipopeptides. Direct binding of at least some of these macromolecules to TLRs has been demonstrated in crystallographic analyses of the relevant complexes. The presence of distinct classes of microbial molecules is sensed by distinct TLRs: for example, TLR4 binds lipopolysaccharides; heterodimers of TLR1 and 2 and TLR2 and 6 bind lipopeptides; and TLR5 binds flagellin. Recognition of all bacterial envelope components by these TLRs occurs at the cell surface.

A second set of TLRs — TLR3, TLR7, and TLR9 — sense the presence of pathogen-derived nucleic acids. They do so not at the cell surface but rather within the endosomal compartments where these receptors reside. Mammalian DNA is methylated at many CpG dinucleotides, whereas microbial DNA generally lacks this modification. TLR9 is activated by unmethylated, CpG-containing microbial DNA. Similarly, double-stranded RNA molecules, replication intermediates of RNA viruses, are present in these virus-infected cells and lead to activation of TLR3. Finally, TLR7 responds to the presence of certain single-stranded RNAs. Thus the full set of mammalian TLRs allows the recognition of a variety of

macromolecules that are diagnostic for the presence of bacterial, viral, or fungal pathogens and parasites such as malaria.

Inflammasome

A variety of intracellular receptors for RNA and DNA have been described that recognize viral RNA and are structurally distinct from TLRs. The list of cytoplasmic receptors capable of recognizing DNA, both pathogen-derived and host DNA-derived, continues to grow. Several of these receptors participate in the assembly of the inflammasome (Figure 24-38), whose major function is the conversion of the enzyme precursor procaspase-1 to the active caspase-1. Caspase-1 is a protease that converts pro-IL-1β into active IL-1β, a cytokine that elicits a strong inflammatory response. Mature IL-1β lacks a signal sequence and is released from producer cells via an unconventional secretory route that involves the formation of pores composed of gasdermin proteins (Figure 24-39). Gasdermins can be converted by caspases from their inactive precursors to the active form to yield pores of a size that allows passage of proteins. In so doing, these pores not only contribute to the release of IL-1β but also to certain forms of cell death called *pyroptosis* ("fiery death," referring to the inflammation that occurs). The core components of inflammasomes are proteins with leucine-rich repeats, members of the neuronal inhibitors of apoptosis (NALP) family of proteins, and the NOD proteins, so named because of the presence of a *n*ucleotide *o*ligomerization *d*omain. Ipaf-1, a protein related to the Apaf-1

molecule involved in apoptosis (see Chapter 22), recruits an adapter protein, ASC, to mediate complex formation with procaspase-1. Assembly of this multisubunit complex allows the conversion of procaspase-1 to active caspase-1 and of pro-IL-1β to IL-1β. Many seemingly unrelated substances can induce assembly and activation of an inflammasome, including silica, uric acid crystals, and asbestos particles. Accordingly, inhibition of the inflammasome signaling cascade, or blocking of the receptor for IL-1β, has shown therapeutic promise for a variety of inflammatory diseases.

FIGURE 24-38 The inflammasome. The inflammasome is a type of complex that senses the presence of cytoplasmic, pathogen-derived nucleic acids. It can also be activated by other danger signals including particulate matter such as uric acid crystals or asbestos. There are close to two dozen proteins that can participate in the formation of these complexes to yield inflammasomes of different composition, two of which are represented here. The fully assembled inflammasome activates caspase-1, the enzyme that converts pro-IL-1β into

the active, cleaved cytokine IL-1β. NALP3, also referred to as *NLRP* = a member of the protein family characterized by the presence of NACHT, LRR, and PYD domains; ASC = apoptosis-associated Speck-like protein containing a CARD (caspase recruitment domain).

FIGURE 24-39 Gasdermin pore structure. Structure of the gasdermin A3 pore determined by cryoelectron microscopy. Gasdermin subunits are converted by caspases upon activation of inflammasomes. The activated subunits self-assemble into a multimeric structure, shown here for 27 subunits of the

gasdermin A3 complex in top and side views. The β barrel domain interacts with the fatty acyl chains of the lipid bilayer and spans the width of the membrane. The resulting pore allows the escape of cellular content, thus contributing to cell death. The large pores formed by an assembled gasdermin complex may facilitate the release into the extracellular environment of intracellularly activated cytokines such as IL-1, a protein that lacks a signal sequence typical of secretory proteins.

TLR Signaling Cascade

As shown in Figure 24-37, engagement of mammalian TLRs leads to recruitment of the adapter protein MyD88, which in turn allows the binding and activation of IRAK (*i*nterleukin 1 *r*eceptor-*a*ssociated *k*inase) proteins. After IRAK phosphorylates TNF-receptor–associated factor 6 (TRAF6), several downstream kinases come into play, leading to release of active NF-κB, a transcription factor, for translocation from the cytoplasm to the nucleus, where NF-κB activates various target genes (see Figure 16-30). These target genes include those encoding the cytokines IL-1β and IL-6, which as we saw contribute to inflammation, as well as the genes for TNF and IL-12. Expression of type I interferons, small proteins with antiviral effects, is also turned on in response to TLR signaling.

Cell responses to TLR signaling are quite diverse. For professional APCs, these responses include production of cytokines as well as the up-regulation of co-stimulatory molecules, the surface proteins important for full activation of T cells that have yet to encounter antigen (referred to as “naive” T cells). TLR signaling allows dendritic cells to migrate from where they encounter a pathogen to the lymph nodes draining that area, where they can interact with naive lymphocytes. Not all activated TLRs evoke an identical response. In dendritic cells, each activated TLR controls production of a particular set of cytokines. For each engaged TLR, the combination of co-stimulatory molecules and the cytokine profile induced by TLR engagement creates a unique activated-dendritic-cell phenotype. The identity of the microbial antigen encountered by a dendritic cell determines the pattern of the TLRs that will be activated. This pattern, in turn, shapes the differentiation pathways of activated dendritic cells, influencing the cytokines produced, the surface molecules displayed, and the chemotactic cues to which the dendritic cells respond. The mode of activation of a dendritic cell and the cytokines it produces in response create a unique local microenvironment in which T cells differentiate. Within this microenvironment, the neighboring T cells acquire the functional characteristics required to fight the infectious agent that led to engagement of the TLRs in the first place.

Engagement of Toll-Like Receptors Leads to Activation of Antigen-Presenting Cells

Professional APCs engage in continuous endocytosis, and in the absence of pathogens, they display at their surface class I and class II MHC molecules loaded with peptides derived from self proteins. In the presence of pathogens, the TLRs on these cells become activated, inducing the APCs to become motile. The cells detach from the surrounding extracellular matrix and start to migrate in the direction of the draining lymph node, following the directional cues provided by chemokines. An activated dendritic cell, for example, reduces its rate of antigen acquisition, up-regulates the activity of endosomal and lysosomal proteases, and increases the transfer of class II MHC–peptide complexes from the loading compartments to the cell surface. Finally, activated professional APCs up-regulate expression of the co-stimulatory molecules CD80 and CD86 (see Figure 24-35), which will allow these APCs to activate T cells more effectively. The initial contact of a professional APC with a pathogen thus results in its migration to the draining lymph node in a state that is fully capable of activating a naive T cell. Antigen is displayed in the form of peptide-MHC complexes, co-stimulatory molecules are abundantly present, and cytokines are secreted that assist in setting up the proper differentiation program for the T cells to be activated.

Antigen-laden dendritic cells engage antigen-specific T cells, which respond by proliferating and differentiating. The cytokines produced in the course of this priming reaction determine whether a CD4-expressing T cell will polarize toward an inflammatory or a classic helper T cell phenotype. If engagement occurs via class I MHC molecules, a CD8-expressing T cell may develop from a precursor cytotoxic T cell into a fully active cytotoxic T cell. Activated T cells are motile and move through the lymph node in search of B cells or enter the circulation to execute effector functions elsewhere in the body.

Production of High-Affinity Antibodies Requires Collaboration Between B and T cells

To generate the high-affinity antibodies that are necessary for tight binding to antigens and effective neutralization of pathogens, B cells require assistance from T cells. B-cell activation requires both a source of antigen to bind to the B-cell receptor (BCR) and the presence of activated antigen-specific T cells (Figure 24-40).

FIGURE 24-40 Collaboration between T and B cells is required to initiate the production of antibodies. *Left:* Activation of T cells by means of antigen-loaded, antigen-presenting dendritic cells (DCs). *Right:* Antigen acquisition by and subsequent activation of B cells to proliferate and differentiate into antibody-secreting plasma cells. Step 1: Professional

antigen-presenting cells (dendritic cells, B cells) acquire antigen. Step **2**: Professional APCs internalize and degrade the antigen and present the resulting antigen-derived peptides, bound to MHC proteins. T-cell activation occurs when dendritic cells present antigen to T cells with receptors that bind the antigen peptide-MHC complex. Step **3a**: Activated T cells engage B cells that express a BCR (surface-bound immunoglobulin) for the antigen and that (like other APCs) present antigen to T cells through peptide-MHC complexes displayed on the surface of the B cell. Step **3b**: T cells that are persistently activated initiate expression of the CD40 ligand (CD40L), a prerequisite for B cells becoming fully activated and turning on the enzymatic machinery (including AID) to initiate class-switch recombination and somatic hypermutation. Step **4a**: A B cell that receives the appropriate instructions from CD4 helper T cells becomes an IgM-secreting plasma cell. Step **4b**: A B cell that receives signals from activated CD4 helper T cells in the form of CD40-CD40L interactions and the appropriate cytokines can switch to other immunoglobulin isotypes and engage in somatic hypermutation, eventually differentiating into a plasma cell.

Soluble antigen reaches the lymph node from the periphery by transport through the afferent lymphatic vessels (see Figure 24-7). Bacterial growth is accompanied by the release of microbial products that can serve as antigens. If the infection is accompanied by local tissue destruction, activation of the complement cascade results in the killing of bacteria and the concomitant release of bacterial proteins, which are also delivered via the lymphatic vessels to the draining lymph node. Antigens covalently modified by proteins of the complement system are superior to their unmodified counterparts in the activation of B cells through engagement of complement receptors on those cells, which serve as co-receptors for the BCR.

B cells that acquire antigen via their BCRs internalize the antibody-antigen complex by endocytosis and proteolytically degrade the

antigen into peptides for presentation to T cells via the class II MHC pathway (see Figure 24-28). B cells that have successfully engaged antigen thus convert it into a call for T-cell help in the form of a class II MHC–peptide complex expressed on the cell surface (Figure 24-40, step **2**). Importantly, the sequence of amino acids on the antigen molecule recognized by the B-cell receptor (a membrane-anchored immunoglobulin) may be quite distinct from the peptide ultimately displayed on the B-cell surface in association with a class II MHC molecule. As long as the B-cell epitope on the antigen and the class II MHC–presented peptide — a T-cell epitope — are physically part of the same antigen, whether linked covalently or held together through noncovalent interactions, successful B-cell differentiation and antibody production can be initiated by T-cell help.

This concept of linked recognition — namely, the engagement of antigen by the B cell's BCR and the display of antigen-derived fragments to T cells by class II MHC molecules — explains why there is a minimum size for molecules that can be used to successfully elicit a high-affinity antibody response, as we will see below. Such immunogenic molecules must fulfill several criteria: they must contain the epitope that binds to the B-cell receptor, they must undergo endocytosis and proteolysis, and a proteolyzed fragment of the protein must bind to the allelic class II MHC molecules available in order to be presented as a class II MHC–peptide complex, which serves as a call for T-cell help.

Often investigators would like to generate an antibody (either polyclonal or monoclonal) that can recognize a short peptide fragment from a larger protein. Such antibodies can be used for a variety of experiments, including detection of a target molecule by immunofluorescence or immunoprecipitation. These antibodies are called *anti-peptide antibodies*. If the peptide alone is used as an immunogen [injected into an animal (e.g., a rabbit, goat, or mouse) to generate antibodies], it probably will not successfully induce robust antibody formation, even though there may be B cells with BCRs that can bind tightly to the peptide. The reason is that it is unlikely that those B cells will be able to generate a complex of a class II MHC with that same peptide and recruit helper T cells to drive proliferation and affinity maturation. For this reason, synthetic peptides used to elicit antibodies are conjugated to carrier proteins to improve their immunogenicity; the carrier proteins serve as the source of peptides for presentation via class II MHC products. Only through recognition of such a class II MHC–peptide complex via its TCR can a T cell provide the help necessary for the B cell to run its complete course of differentiation leading to robust, high-affinity antibody production.

This concept applies equally to B cells capable of recognizing particular modifications on proteins or peptides. Antibodies that recognize the phosphorylated form of a kinase are commonly raised by immunization of experimental animals with the phosphorylated peptide in question, conjugated to a carrier protein. An appropriately specific BCR recognizes the phosphorylated site on the peptide of interest, internalizes the phosphorylated peptide and carrier, and generates a complex set of peptides by endosomal proteolysis of the carrier protein. Among these peptides, there should be at least one that can bind to the class II MHC molecules carried by that B cell. If properly displayed at the surface of the B cell, this class II MHC–peptide complex becomes the call for T-cell help, which is provided by helper T cells equipped with receptors capable of recognizing the complex of class II MHC molecule and carrier-derived peptide. ■

The helper T cell identifies, via its TCR, an antigen-experienced B cell by means of the class II MHC–peptide complex the B cell displays (Figure 24-40, step **3a**). The B cell also displays co-stimulatory molecules and receptors for cytokines produced by the activated T cell (e.g., IL-4). After interacting with T cells, these B cells proliferate. Some of them differentiate into plasma cells; others are set aside and become memory B cells. The first wave of antibodies they produce is always IgM (Figure 24-40, step **4a**). Class switching to other isotypes and somatic hypermutation (necessary for the generation and selection of high-affinity antibodies) require the persistence of antigen or repeated exposure to antigen. In

addition to cytokines, B cells require cell-cell contacts to initiate these processes. These contacts involve the CD40 protein on B cells and CD40L on T cells (Figure 24-40, step **3b**); these proteins are members of the TNF–TNF receptor family. Work on HIV suggests that extensive somatic hypermutation is a prerequisite for the generation of broadly neutralizing antibodies — antibodies that can neutralize a broad selection of highly variable HIV isolates. More insight into the control of somatic hypermutation will be required to understand the nature of the antigen(s) capable of eliciting such desirable antibodies as a prophylactic strategy.

Vaccines Elicit Protective Immunity Against a Variety of Pathogens

Arguably the most important practical application of immunological principles is the vaccine. Vaccines are materials that are designed to be innocuous but that can elicit an immune response for the purpose of providing protection against a challenge with the virulent version of a pathogen (Figure 24-41). It is not always known why vaccines are as successful as they are, but in many cases, the ability to raise antibodies that can neutralize a pathogen (viruses) or that show microbicidal effects (bacteria) are good indicators of successful vaccination.

FIGURE 24-41 Time course of a viral infection. The initial antiviral response, seen when the number of infectious particles rises, includes activation of natural killer (NK) cells and production of type I interferons. These responses are part of the innate immune response. The production of antibodies and the activation of cytotoxic T cells (CTLs) follow, eventually clearing the infection. Re-exposure to the same virus leads to more rapid and more pronounced production of antibodies and to more rapid activation of cytotoxic T cells. A successful vaccine induces an immune response similar in some respects to that following initial exposure to a pathogen, but without causing significant symptoms of disease. If a vaccinated person is subsequently exposed to the same pathogen, the adaptive immune system is primed to respond quickly and strongly.

Several strategies can lead to a successful vaccine. Serial passage of a pathogen in tissue culture or from animal to animal often leads to *attenuation*; the molecular basis of attenuation is not well understood. Vaccines may be composed of live attenuated variants of more virulent pathogens. The attenuated version of the pathogen causes a mild form of the disease or causes no symptoms at all. However, by recruiting all the component parts of the adaptive immune system, such live attenuated vaccines can elicit protective levels of antibodies. These antibody levels may wane with advancing age because the lymphocytes responsible for immunological memory may have a finite life span, so repeated immunizations (booster injections) are often required to maintain full protection. Live attenuated vaccines are in use against flu, measles, mumps, and tuberculosis. In the latter case, an attenuated strain of the mycobacterium that causes the disease is used (Bacille Calmette-Guerin; BCG). Although live attenuated poliovirus was used as a vaccine until recently, its use was discontinued because the risk of reemergence, by mutation, of more virulent strains of the poliovirus outweighed the benefit. Currently, killed poliovirus is used as the vaccine of choice in the United States and Europe, although live attenuated poliovirus vaccines continue to be used elsewhere.

Vaccines based on the cowpox virus, a close relative of the human variola virus that causes smallpox, have been used successfully to eradicate smallpox; the first successful elimination of an infectious disease. Attempts to achieve a similar feat for polio are nearing

completion, but socioeconomic and political factors or armed conflict often complicate the administration of vaccines, leading to reemergence of the disease, as seen recently in Asia.

Spurious claims that vaccines may cause autism have led to skepticism among some people regarding the benefits of childhood vaccinations against serious childhood diseases such as rubella and mumps. The number of vaccinated individuals drops when parents choose not to vaccinate their children. As a consequence, the type of protection referred to as *herd immunity* wanes and exposes entire populations to the resurgence of diseases easily controlled by childhood vaccination. There is no evidence that childhood vaccinations are in any way connected to the onset or severity of autism or related disorders.

The other major type of vaccine is called a *subunit vaccine*. Rather than attenuated or killed pathogen, only one or several of the pathogen's components are used to elicit immunity. In certain cases, this approach is sufficient to afford lasting protection against a challenge with the live, virulent source of the antigen used for vaccination. It has been successful in preventing infections with the hepatitis B virus. The commonly used flu vaccines are composed mainly of the envelope proteins neuraminidase and hemagglutinin (see Figure 3-10); these vaccines elicit neutralizing antibodies. For the vaccine against human papillomavirus HPV 16, a virus that causes cervical cancer, viruslike particles composed of the virus's

capsid structural proteins but devoid of the viral DNA are generated; these particles are noninfectious, yet in many respects mimic the intact virion. The HPV vaccine now licensed for use in humans is expected to reduce the incidence of cervical cancer in susceptible populations by perhaps as much as 80 percent, the first example of a vaccine that prevents a particular type of cancer.

From a public health perspective, cheaply produced and widely distributed vaccines are formidable tools for preventing or even eradicating communicable diseases. Current efforts are aimed at producing vaccines against diseases for which no other suitable therapies are available (Ebola virus, coronaviruses such as the SARS-CoV-2 virus responsible for the 2020 pandemic) or where socioeconomic conditions have made the distribution of drugs problematic (malaria, HIV). With a more complete understanding of how the immune system operates, it should be possible to improve on the design of existing vaccines and extend these principles to diseases for which no successful vaccines are currently available. A remaining challenge is the massive genetic variation that pathogens can acquire: the error-prone reverse transcriptase of HIV introduces mutations with every successive cycle of viral replication, creating untold numbers of variants. Viable variants that carry such mutations may escape detection by the immune system. The design of effective vaccines, not only against HIV but also influenza virus, must therefore be focused on those structural elements that do not tolerate mutations and that can be seen by the adaptive immune system. ■

The Immune System Defends Against Cancer

The immune system not only defends against the immediate consequences of infection with pathogens but may also help in warding off cancer. As we have seen, the adaptive immune system is purged of many self-reactive B and T cells by negative selection. Self-reactive lymphocytes that escape this process are usually silenced because they are not provided with the appropriate co-stimulatory signals. Conditions that lead to severe immunosuppression, such as a genetic lesion in the RAG somatic recombination machinery or immunodeficiency caused by infection with HIV, confer an increased risk of cancer, not only for cancers caused by transforming viruses but also for those elicited by carcinogens. This observation establishes a role for the immune response in keeping precancerous cells in check.

Recall that B and T cells require activation not only via their antigen-specific receptors, but also by a second, co-stimulatory signal (e.g., binding of CD28 on T cells to CD80 or CD86 on APCs; see Figure 24-35). Withholding of this co-stimulatory signal silences, or anergizes, any self-reactive lymphocyte that escaped deletion in the course of T-cell selection. Because tumor cells are exceedingly similar to the progenitors that give rise to them (see Chapter 25), with only those few mutations ("driver mutations") required to cause cancer, it is not immediately obvious how immune recognition aids in the

eradication of (pre) malignant cells before they have chance to grow into larger tumors.

Somatic Mutations Allow Immune Recognition of Tumor Cells

Nonetheless, somatic mutations in the developing tumor cell — even those that are adventitious and do not directly contribute to causing cancer — can create so-called neo-antigens that may be recognized by antigen-specific receptors on T cells. Chemical mutagens, as experienced by heavy smokers who expose their lungs to tobacco products, not only cause mutations in genes that then drive tumorigenesis, but also cause mutations in other genes (passenger mutations), providing a rich spectrum of altered gene products to which the developing immune system was never exposed. If there is no immune tolerance for these mutagen-induced neo-antigens, they may serve as targets for recognition by the host's immune system.

Often the deregulation of gene expression that accompanies a transformed phenotype results in re-expression of differentiation antigens characteristic of a much earlier developmental state. If these differentiation antigens were expressed at a stage of development when the immune system had not yet fully matured, immune tolerance for such differentiation antigens may not have been established. These antigens may therefore be targets for immune recognition. Finally, the levels of certain gene products may no longer be properly regulated in cancer cells and may begin

to exceed a threshold required for immune recognition, notwithstanding the fact that they are proteins normally made by the host, albeit at much reduced levels.

In summary, because cancer can be considered a disease caused first and foremost by mutations, whose effects are modified by epigenetic events (see Chapter 25), there is the potential for immune recognition of cancer cells. Furthermore, in much the same way that an immune response against a virus or a bacterium can result in the outgrowth of variants that are no longer recognized by the immune system, selective pressure exerted by the immune system may also lead to variants of cancer cells that have lost expression of a possible tumor antigen. For example, many colon cancers show reduced levels, if not complete loss of expression, of class I MHC products, and are thus rendered invisible to cytotoxic T cells.

Antibodies Against CTLA4, PD-1, and PD-L1 Are the Basis of Cancer Immunotherapy

The tumor microenvironment is composed of stromal cells: fibroblasts and myeloid-derived cells, including macrophages. Lymphocytes are known to invade tumors, as do neutrophils. The interplay between tumor cells and the microenvironment in which these cells reside can create immunosuppressive conditions that preclude a successful anti-tumor immune response, even if the tumor cells themselves are sufficiently antigenically distinct to be recognized as such. Important players in establishing an

immunosuppressive environment are molecules now referred to as *immunological checkpoints*, such as CTLA4, the expression of which on T cells increases as T cells undergo full activation and maturation. Normally, CTLA4 would play a role in terminating an immune response, but its expression on the surface of tumor-specific T cells would compromise their anti-tumor activity. Moreover, the thymus and peripheral lymphoid compartments produce Treg cells, which are capable of suppressing the activity of other T cells. An abundance of Treg cells would keep other T cells from attacking a tumor. By the same logic, these Treg cells may keep potentially self-reactive T cells in check as a means of preventing the onset or reducing the severity of autoimmune disease.

Two key inhibitors of immune responses are PD-1 on T cells and PD-L1 on T-cell targets. Binding of PD-L1 on a tumor cell to PD-1 on a T cell that recognizes a tumor neo-antigen inhibits T-cell functions, including its ability to kill the tumor cell. A spectacular breakthrough in the treatment of cancer is the use of antibodies that target the inhibitory T-cell proteins CTLA4 and PD-1 proteins as well as PD-L1, often present on certain tumor cells. Some 30 percent of patients with metastatic melanoma, refractory to other forms of therapy, respond to treatment with antibodies against CTLA4, PD-1, or PD-L1, which has resulted in complete remissions and even cures. Similar approaches are underway to treat different forms of lung and renal cancer. Treatment with anti-CTLA4 apparently broadens the repertoire of cytotoxic T cells capable of recognizing tumor antigens as well as suppressing the activity of Treg cells. Treatment with anti-PD-1 or anti PD-L1 enhances T-cell recognition of tumors. It is perhaps ironic that smokers with the heaviest exposure to tobacco products may benefit the most from these forms of treatment because of the high mutational load in their cancers. ■

KEY CONCEPTS OF SECTION 24.6

Collaboration of Immune-System Cells in the Adaptive Response

- Antigen-presenting cells such as dendritic cells require activation by means of signals delivered to their Toll-like receptors and other pattern recognition receptors. These receptors are broadly specific for macromolecules produced by bacteria and viruses.

Their engagement activates the NF-κB signaling pathway, whose outputs include the synthesis of inflammatory cytokines (see Figure 24-37).

- Upon activation, dendritic cells become migratory and move to lymph nodes, ready for their encounter with T cells. Activation of dendritic cells also increases their display of MHC-peptide complexes and expression of co-stimulatory molecules required for initiation of a T-cell response.
- B cells require the assistance of T cells to execute their full differentiation program into plasma cells. Antigen-specific help is provided to B cells by activated T cells, which recognize class II MHC–peptide complexes on the surfaces of B cells. These B cells generate the relevant MHC-peptide complexes by internalizing antigen via BCR-mediated endocytosis, followed by antigen processing and presentation via the class II MHC pathway (see Figure 24-40).
- In addition to cytokines produced by activated T cells, B cells require cell-cell contact to initiate somatic hypermutation and class-switch recombination. This contact involves CD40 on B cells and CD40L on T cells.
- Important applications of the immunological concept of collaboration between T and B cells include vaccines. The most common forms of vaccines are live attenuated viruses or bacteria, which can evoke a protective immune response without causing pathology, and subunit vaccines.
- The adaptive immune system can sometimes distinguish between normal cells and their cancerous counterparts. What complicates immune-system detection of cancer cells are the often relatively minor differences between normal and transformed cells.
- Immunological checkpoints dampen the activity of antigen-specific T cells under normal circumstances as a means of turning off or controlling an immune response.

Review the Concepts

1. Describe the ways in which each of the following pathogens can disarm their host's immune system or manipulate it to their own advantage:
   a. Pathogenic strains of *Staphylococcus aureus*, a Gram-positive bacterium that replicates extracellularly and secretes cytotoxic products (toxins)
   b. Enveloped viruses such as HIV (see Section 5.7)
2. Trace the movement of leukocytes as they perform their functions throughout the body.
3. Identify the major mechanical and chemical defenses that protect internal tissues from microbial attack.
4. Compare and contrast the classical pathway of complement activation with the alternative pathway.
5. What is opsonization? What is the role of antibodies in this process?
6. In B cells, what mechanism ensures that only rearranged V genes are transcribed?
7. What prevents further rearrangement of immunoglobulin heavy-chain gene segments in a pre-B cell once a productive heavy-chain rearrangement has occurred?
8. How and why do B cells undergo a class switch from producing IgM antibodies to any of the other Ig isotypes?
9. What biochemical mechanism underlies affinity maturation of the antibody response?

10. Compare and contrast the structures of class I and class II MHC molecules. What kinds of cells express each class of MHC molecule? What are the functions of these cells?
11. Describe the six steps in antigen processing and presentation via the class I MHC pathway.
12. Describe the six steps in antigen processing and presentation via the class II MHC pathway.
13. What prevents self-reactive T cells from leaving the thymus?
14. Explain why T-cell–mediated autoimmune diseases are associated with particular alleles of class II MHC genes.
15. How are antigen-presenting cells and helper T cells involved in B-cell activation?
16. Outline the events in the innate and adaptive immune responses, from when a pathogen invades to clearance of the pathogen.
17. Define passive immunization and give an example.
18. How would you design a vaccine that protects against HIV infection without the possibility of infecting the patient?
19. The annual flu shot is composed of either live attenuated influenza virus or influenza subunits (the envelope proteins neuraminidase and hemagglutinin). How does the annual flu shot protect you against infection?
20. Design a laboratory protocol to develop a monoclonal or polyclonal antibody against a protein of interest (see Section 4.1).
21. Consider a person without any functioning plasma cells. What effects would this condition have on the person's

adaptive immune system? Innate immune system?

CHAPTER 25

Cancer

Image provided by Elen Torres and Stefani Spranger, MIT.

Cells of the immune system often interact with cancer cells within the tumor microenvironment. This section of a lung adenocarcinoma shows all cell nuclei (blue), tumor

cells (green) and $CD8^+$ T cells (magenta). Note the tendency of the T cells to be in contact with tumor cells.

OUTLINE

25.1 How Tumor Cells Differ from Normal Cells
25.2 Genetic and Genomic Basis of Cancer
25.3 Dysregulation of Cell Growth and Developmental Pathways Initiates Tumorigenesis
25.4 Evasion of Programmed Cell Death and Immune Surveillance Processes

Cancer, described in the simplest terms, arises as a disease when normal somatic cells of the body acquire a set of mutations that cause them to escape from the orderly patterns of tissue development and to grow and spread through the body. Because there are many ways that loss of normal developmental regulation can lead to uncontrolled growth, cancer is actually many different diseases depending upon the origin of the cancer cells. Tumors derived from epithelial tissues such as endoderm (gut epithelium) or ectoderm (skin and neural epithelia) are classified as **carcinomas**, whereas tumors derived from mesodermal tissues (muscle, bone, cartilage and connective tissue precursors) are classified as **sarcomas**. Many tumors form solid masses, but tumors of the blood and bone marrow, such as the **leukemias** and **lymphomas**, can grow as individual cells circulating in the blood. The classification of cancer types is further subdivided according to the exact cell type of origin and sometimes even according to the types of mutations that have caused dysfunction in a particular cell type. There are about 200 types of cancer based on histological examination of tumor

cells; the number of distinct types of cancer that are recognized is increasing as differences between cancer cells can be discerned at a molecular level.

Despite the wide variety of different types of cancer, all cancers are thought to arise by the same process, called **oncogenesis** or **tumorigenesis**, which begins with a single mutation in a somatic cell that eventually develops into a clone of cancer cells possessing many different oncogenic mutations. Although it is possible to imagine how one of the approximately 10^{12} dividing cells in the body could be struck by even a very rare mutational event, it seems inconceivable that a clone of cells could by chance alone acquire a whole set of highly specific mutations needed for all of the phenotypic properties of a cancer cell. The answer to this puzzle is that oncogenesis is the grim result of a version of natural selection in which cells that proliferate a bit more rapidly than their neighbors, or do not undergo apoptosis when they should, have greater opportunity to undergo further genetic changes. Most tumors develop slowly, acquiring additional oncogenic mutations by selection over a span of many years.

Figure 25-1 shows an outline for understanding how cancer progresses from an initiating mutation to a full tumor by the acquisition of successive mutations in a clone of cells successively acquiring oncogenic mutations. Usually, by the time a tumor is detected and its genome can be analyzed, so many mutations have

accumulated that it is not possible to identify with certainty the original mutation that started a cell down the path to cancer. Nevertheless, two general types of mutations are known to be capable of initiating oncogenesis. The first type of initiating mutation may affect one of the many signal transduction pathways that regulate cell growth. Such mutations could either inappropriately activate a growth-promoting pathway or could inactivate a growth-inhibiting pathway. In either case, the mutant cells would grow more rapidly than their well-regulated neighbors and thus provide more opportunity for those cells to acquire additional oncogenic mutations. The second type of initiating mutation impairs the ability of the cell to repair damage to DNA caused by a **mutagen** or by an error in DNA replication. Such mutations could be in the DNA repair enzymes themselves or could prevent the arrest of the cell at one of the cell cycle checkpoints to allow the repair to take place (see Chapter 20). As described in Chapter 5, DNA replication and cell division are necessary for damage to DNA to be converted to a mutation in the base sequence. This fundamental relationship between cell division and mutagenesis is one of the reasons why cells in actively dividing tissues are the most susceptible to acquiring oncogenic mutations and therefore generally the most prone to form tumors.

FIGURE 25-1 General framework for the evolutionary progression of cancer. The progression of cancer from a normal somatic cell to a full-grown tumor can be thought to take place in four stages. Step 1: Initiation. Except in rare cases in which cancer is caused by a singular genetic event, such as infection by a tumor virus, we usually cannot pinpoint the initiating event but a somatic mutation is usually suspected. Step 2: Cancer progression. Precancerous cells acquire mutations that dysregulate growth-control pathways, causing inappropriate cell proliferation. In addition, they acquire mutations that cause genome instability and propensity to acquire yet more mutations, mainly by loss of the DNA damage checkpoint. Most cancers progress by a process of natural selection, sequentially acquiring multiple such mutations in different pathways. Step 3: Evasion of cancer cell elimination. Precancerous cells are normally removed from the body by either apoptosis or immune-surveillance processes. To progress beyond this stage, tumor cells must acquire additional somatic mutations that allow them to evade these systems. Step 4: Tumor growth and dispersal. Continued growth of a tumor requires a blood supply and tumor cells must acquire yet more changes that promote angiogenesis. To spread throughout the body by metastasis, cells from a solid tumor must acquire the ability to migrate from their original site and adhere at a new location in the body.

The clonal descendants of an initial mutant are susceptible to acquiring additional oncogenic mutations of either a type that promotes cell proliferation or that inhibits DNA repair. These additional mutations in turn increase the propensity for yet more oncogenic mutations. Each iteration of this cycle of mutation and selection for more rapidly growing cells produce cellular

descendants exhibiting successively more uncontrolled growth and more defects in the genome. Tumors are usually detected only after they have reached 1 cm^3 in size, by which time their cells have undergone many cycles of error-prone replication and their genomes will carry many different single-base changes due to errors in replication and chromosome rearrangements due to erroneous repair of breaks in the DNA. The base sequence of cancer cell genomes usually reveals a profusion of mutations; it is often difficult to distinguish mutations that drive the oncogenic process from mutations that arose fortuitously but do not themselves contribute to oncogenic progression.

Other oncogenic mutations enable cancer cells to evade the two major systems that cause removal of aberrant cells from the body. Mammalian cells are normally able to monitor the integrity of their genome, and if they suffer a major, irreparable aberration in genome structure will enter a cell death program (see Chapter 22) that will cause them to be eliminated before they can become cancerous. The precancerous cells that do survive to become tumors have lost one or more of the key elements of the programmed cell death pathway. Another class of oncogenic mutations often found in tumors has allowed the cancer cells to evade surveillance by T cells of the immune system. As a cancer cell accumulates an increasing burden of mutations in the genome, the proteins of the cell will increasingly carry amino acid substitutions, truncations, and domain rearrangements that will eventually cause a cancer cell to

appear as foreign to the immune system. Specific mutations in cancer cells allow them to avoid immune detection and destruction.

The growth of a mass of rapidly dividing cells will reach a limit simply because the cells on the inside of the mass are restricted by diffusion for the availability of nutrients and oxygen. For a tumor to grow beyond the dimensions of several millimeters requires that the tumor cells be supplied with blood. Accordingly, a fourth type of oncogenic mutation found in solid tumors enables the tumor cells to signal for formation of blood vessels by secreting certain growth factors. In addition to the transformed cancer cells, tumors usually recruit numerous cells that are not mutated and that form differentiated structures in response to signals emanating from the cancer cells. Because tumors contain multiple cell types and structures, they more closely resemble developed organs than a clonal mass of cells. Finally, due to yet other oncogenic mutations, tumor cells often have acquired the ability to detach from the primary tumor, to enter circulating blood or lymphatic systems and adhere to a new site and form a secondary tumor in a different tissue. The capability of a tumor to spread throughout the body in this way is known as **metastasis** and is a hallmark of the deadliest forms of cancer.

This basic outline of the origin, progression, growth, and spread of cancer shows why cancer is such a difficult disease to treat. Because cancer cells are derived from normal somatic cells, it is generally not possible to kill cancer cells selectively without to some extent

killing normal cells as well. Most cancer therapy aims at killing rapidly dividing cells that cannot repair their DNA efficiently. For example, alkylating agents that cause cross-links in DNA are among the most commonly used anticancer chemotherapeutic compounds that preferentially kill cells that are actively undergoing DNA replication but that have lost the ability to repair cross-linked and broken DNA. Even the most effective anticancer compounds cause tremendous collateral damage to actively dividing, normal cells, such as the dividing cells in the hair follicles, bone marrow, and immune system, causing hair loss, anemia, and susceptibility to infections.

Another avenue to cancer therapy is to reverse the effects of oncogenic mutations by, for example, inhibiting the product of an overexpressed oncogene. This type of targeted therapy is effective at treating rare forms of cancer that arise because of a single oncogenic event. As we will see, the vast majority of cancers have acquired multiple oncogenic mutations in different pathways for cell growth, DNA repair, and programmed cell death and there are no prospects yet for a magic bullet that can simultaneously reverse the dysregulation of multiple pathways.

Currently, our understanding of how cancer develops at the cellular level offers the most promise for early diagnosis and prevention of the disease. All of the known oncogenic mutations as well as their physiological consequences can be thought of as molecular markers that could allow early detection of the presence of precancerous

cells. In the early stages of progression of the disease, precancerous cells are likely to be the most vulnerable to correction by a drug targeted to a specific pathway or by elimination by heightened immune surveillance. We know that most cancers develop in stages over a long period of time; detection of the first steps of oncogenesis should afford significant opportunities to intervene.

In this chapter, we first introduce the properties of tumor cells, illustrating how the genome, cellular metabolism, regulation of growth and proliferation, and morphology all can be altered in cancer. We will also see how the interaction of cancer cells with their environment enables development of large tumors and the spread of cancer by metastasis. We then discuss the genetic and genomic basis of cancer, how cancer can originate with inherited mutations or by somatic mutations caused by carcinogens and how the breakdown of genome maintenance functions contributes to tumorigenesis. Next we consider the general types of genetic changes affecting both growth-promoting and growth-inhibiting processes that can result in excess cell proliferation. We conclude the chapter with a discussion of how cancer cells acquire mutations that allow them to escape from programmed cell death and immune surveillance. We will end with promising new ways to treat mature tumors based on activation of the immune system to recognize and destroy cancer cells, known as *cancer immunotherapy*.

25.1 How Tumor Cells Differ from Normal Cells

Before examining the genetic basis of cancer in detail, let's consider the general properties of tumor cells that distinguish them from normal cells. The change from a normal cell to a cancer cell commonly involves multiple steps, each one adding properties that make cells more likely to grow into a tumor. The genetic changes that underlie oncogenesis alter several fundamental properties of cells, allowing those cells to evade normal growth controls, modulating their tissue microenvironment, and ultimately conferring the full cancer phenotype (see Figure 25-1). Cancer cells acquire a drive to proliferate that does not require an external inducing signal. They fail to sense signals that restrict cell division, and they survive when they should die. They often change their attachment to surrounding cells or to the extracellular matrix, breaking loose to move away from their tissue of origin. Solid tumors characteristically outgrow their initial blood supply and become *hypoxic* (oxygen starved), so to grow to more than a small size, tumors must obtain an additional source of blood flow. They often do so by inducing the growth of blood vessels into the tumor. As cancer progresses, further adaptations are acquired by selection allowing growth and invasion of surrounding tissues, often spreading to distant sites in the body.

In this section, we describe the characteristics of cancer cells. We first discuss the changes in the cancer cell's genetic makeup that affect virtually all cellular functions, allowing the cancer cell to escape proliferation regulation and acquire the ability to divide indefinitely. We then see how the genetic changes in a tumor cell and its interactions with its environment facilitate its escape from the constraints of the tissue it was once a part of and allow it to invade neighboring tissues and colonize distant sites in the body.

The Genetic Makeup of Most Cancer Cells Is Dramatically Altered

At the turn of the twentieth century, David von Hansemann and Theodor Boveri first documented what we now know to be an almost universal feature of cancer cells: their entire genetic makeup differs dramatically from that of normal cells. Chromosomes from cancer cells stained to be visible in the light microscope often show a highly altered karyotype and large chromosomal amplifications and deletions, translocations, and aberrant numbers of chromosomes — generally too many, a condition known as *aneuploidy*. Typical cancer cells exhibit whole chromosome or chromosome arm gains and losses involving a quarter of their genome (Figure 25-2). The advent of efficient next generation DNA-sequencing methods has allowed complete cancer genome sequences to be obtained from thousands of different tumors. In

addition to gross chromosomal abnormalities, sequencing reveals single-base mutations and small, local amplifications and deletions often affecting about 10 percent of the cancer cell's genome (Figure 25-3). Perhaps the most surprising result revealed by the sequencing of cancers is the high degree of variation in mutation rates across different cancers. Mutations are rare in pediatric cancers, with substitution rates as low as a few hundred base changes per genome, but those rates may be as high as 500,000 base changes per genome in mutagen-induced cancers such as certain lung cancers and melanomas. As we will see in Section 25.2, the frequency and type of genomic mutations in a given tumor can often be traced to the presence of mutations in DNA repair pathways. These genetic changes affect virtually all aspects of cellular homeostasis, proliferation, tissue organization, and migratory properties as well as survival and proliferation at foreign sites in the body.

FIGURE 25-2 Cancers often have highly abnormal karyotypes. Image of chromosomes obtained from an SW403 colorectal adenocarcinoma cell line. Chromosomes are arranged and color coded according to labeling with probes specific for each of the 24 chromosomes. Two characteristics of the cancer cells are evident. First, a normal karyoptype would contain exactly two copies of each chromosome and the cancer cells contain one or two extra copies of many of the chromosomes. Second, many chromosomes are composites of pieces from different chromosomes, which result from translocation events.

[From W. M. Abdel-Rahman et al., 2001, "Spectral Karyotyping Suggests Additional Subsets of Colorectal Cancers Characterized by Pattern of Chromosome Rearrangement." *Proc. Nat'l Acad. Sci. USA* **98**(5):2538–2543, Fig. 3c. Copyright (2001) National Academy of Sciences, U.S.A.]

FIGURE 25-3 Cancer genome sequencing reveals thousands of sequence alterations. The complete genome sequence of the MCF-7 adenocarcinoma breast cancer cell line displayed as a Circos plot. The 23 chromosomes are arranged around the outside ring. In the next ring, DNA copy number is represented by increases (green) or decreases (red) from the normal 2n (diploid) number of copies, showing that most of the MCF-7 genome has an abnormal copy number. Intrachromosomal and interchromosomal rearrangements are represented respectively by blue and red arcs. A total of 157 chromosomal breakpoints were found.

Uncontrolled Proliferation Is a Universal Trait of Cancer

In normal tissues, cell proliferation is a highly controlled process. Growth-promoting factors are released in a highly controlled fashion to ensure that target cells proliferate only as needed to replenish a tissue. A universal feature of cancer cells is that they have acquired oncogenic mutations that allow them to escape these tight controls and to proliferate continuously and indefinitely. Here we will briefly introduce three of the most common *oncogenic mutations* as illustrative examples, and in Sections 25.3 and 25.4, we will develop a more comprehensive picture of the ways that different mutations can enable cancer cell proliferation.

The **Ras protein** described in Chapter 16 acts a GTPase switch in many of the signaling pathways that receive growth stimulatory signals via a receptor tyrosine kinase. Ras activates the MAP kinase signal transduction pathway that in turn activates many transcription factors regulating aspects of cell proliferation. The first oncogenic mutation to be described is a point mutation in the *Ras* gene that causes constitutive activation of the MAP kinase pathway. This pathway normally is only activated when a growth factor is present in the cell's environment. Thus precancerous cells that carry an oncogenic Ras mutation proliferate as if they are continually receiving a growth signal.

Most human tumors have oncogenic mutations in **p53** or in proteins that regulate p53 activity. Normally, p53 plays a major role in maintaining the integrity of the genome. As described in Chapter 19, when DNA damage is first detected in a cell, p53 is responsible for causing cell cycle arrest before M phase, giving repair enzymes sufficient time to correct the damage before the cell cycle continues. If the DNA damage cannot be repaired, p53 will eventually activate apoptosis to ensure that cells with a compromised genome are eliminated from the body. Precancerous cells that have insufficient p53 activity continue to divide even when their DNA is badly damaged. Such unchecked cell divisions destabilize the genome and greatly accelerate the acquisition of additional oncogenic mutations.

A third example of oncogenic mutations that allows uncontrolled cell proliferation commonly found in tumors are DNA rearrangements that cause increased expression of **telomerase**, the enzyme responsible for adding telomeres, short tandem DNA sequences, to the ends of linear chromosomes. As discussed in Chapter 7, telomeres become shorter every time a chromosome is replicated. Most human somatic cells produce only a small amount of telomerase and uncontrolled proliferation would eventually lead to extensive shortening of telomeres, which is recognized by the cell as a double-strand break that consequently triggers cell cycle arrest and apoptosis. Tumor cells overcome this fate by up-regulating telomerase expression to produce a state of replicative immortality.

Cellular Housekeeping Functions Are Fundamentally Altered in Cancer Cells

Cancer cells can often be distinguished from normal cells by microscopic examination. They are usually less well differentiated than normal cells. Cancer cells frequently exhibit the characteristics of non-cancerous rapidly growing cells: a high nucleus-to-cytoplasm ratio, prominent nucleoli, an increased frequency of mitotic cells, and relatively little specialized structure.

Tumor cells differ from normal cells not only in their appearance, but in their entire protein composition. Losses and gains of whole chromosomes or chromosome parts are characteristic of cancer cells and have a profound effect on the protein composition of the cell and hence on many cellular functions. Imbalances in the composition of multiprotein particles cause many proteins to remain only partially folded; this in turn induces a stress response, similar to that caused by raising the cell to an elevated temperature (see Chapter 21), aimed at offsetting these protein imbalances. As a result, cancer cells rely heavily on protein-folding chaperones and degradation mechanisms, including proteasomes, for their survival as a direct result of their dramatically altered chromosome composition.

Another hallmark of cancer cells is their dependence on an energy-generating pathway that resting cells only use if they are deprived of

oxygen. Most normal differentiated cells rely on relatively efficient mitochondrial oxidative phosphorylation to satisfy their energy needs. Cells metabolize glucose to carbon dioxide by oxidation of pyruvate through the tricarboxylic acid (TCA) cycle in the mitochondria (see Chapter 12). Only under anaerobic conditions do normal resting cells undergo anaerobic glycolysis and produce large amounts of lactate. Most cancer cells, however, rely on glycolysis for energy production irrespective of whether oxygen levels are high or low (Figure 25-4). The use of glycolysis to produce energy even in the presence of oxygen, called *aerobic* glycolysis, was first discovered in cancer cells by the biochemist Otto Warburg and is therefore called the **Warburg effect**. Aerobic glycolysis generates only 2 ATP molecules per molecule of glucose and appears to be much less efficient than oxidative phosphorylation, which generates up to 36 molecules of ATP per molecule of glucose. However, by not using the TCA cycle for generating energy, proliferating cells can instead utilize the molecules in the TCA cycle and their precursors to synthesize nucleotides, amino acids, and lipids. This rewiring of glucose metabolism diverts the flow of metabolic intermediates away from ATP synthesis and toward the production of cellular building blocks, a balance more favorable for rapid cell growth.

FIGURE 25-4 Energy production in cancer cells by aerobic glycolysis. In the presence of oxygen, nonproliferating (differentiated) cells metabolize glucose into pyruvate via glycolysis. Pyruvate is then transported into mitochondria, where it is fed into the TCA cycle. Oxygen is required as the final electron acceptor during oxidative phosphorylation. Thus when oxygen is limiting, cells metabolize pyruvate into lactate, allowing glycolysis to continue by cycling NADH back to NAD^+. Cancer cells and proliferating cells convert most glucose to lactate regardless of whether oxygen is present or not. The production of lactate in the presence of oxygen is called *aerobic* glycolysis.

[Data from M. G. Vander Heiden, L. C. Cantley, and C. B. Thompson, 2009, *Science* **324**:1029.]

Not only do cancer cells rewire their metabolic pathways, but they also produce increased levels of some metabolites and metabolic by-

products. These so-called *onco-metabolites* directly or indirectly alter patterns of gene expression, including genes involved in blood vessel formation.

Cancer Cells Exhibit Altered Cell-Cell Interactions to Form Heterogeneous Organs

Many human cell types grow in well-ordered sheets. Cells do not continue to divide and grow outside the plane of the sheet because of a phenomenon of *contact inhibition*, which causes arrest in the G_0 phase of the cell cycle when a cell is completely surrounded by other cells. Precancerous cells have lost contact inhibition, are less adherent and more rounded than normal cells, and will continue to divide as a three-dimensional cluster of cells (a *focus*) that can be recognized under a microscope. Adhesion molecules such as E-cadherin, cell polarity factors, actin cytoskeleton regulators, and the Hippo pathway (see Chapter 21) all function in mediating cell cycle arrest when cell-cell contacts are established. However, the exact mechanisms whereby this occurs, and how these pathways are disrupted in cancer, remain to be worked out.

Not all tumors are made up of uniform cells, even if they originated from a single initiating cell. In some types of tumors, for example, only certain tumor cells, called **cancer stem cells**, are capable of

seeding a new tumor. Within these tumors, some cells cease dividing, while others can continue cancerous growth. The latter, of course, are the most dangerous and the most important to destroy with anticancer treatments. Cancer stem cells are thought to give rise to some cells with high replicative capabilities and others with more limited replicative potential. The origins of these cancer stem cells are not clear. In some cancers, a normal tissue stem cell may give rise to the cancer stem cells. In others, dedifferentiation of terminally differentiated cells to form progenitor cells may give rise to cancer stem cells. Irrespective of their origin, cancer stem cells share gene expression signatures with normal tissue stem cells, leading to their designation as stem cell-like cells.

The immediate environment of a tumor — the **tumor microenvironment** — contributes to the heterogeneity of cells within the tumor, influencing the behavior of the cancer stem cells and the tumor cells in general. Some neighboring cells may be more conducive to tumor growth than others. The importance of the tumor microenvironment extends to one of the most common environmental influences on a tumor cell: inflammatory cells. It is now widely accepted that cells of the immune system interact with the tumor. As we detail in Section 25.4, $CD8^+$ cytotoxic T lymphocytes and natural killer cells surround and often migrate into the tumor, where they can inhibit tumor formation. Mice deficient in these and other components of the immune system are more prone to carcinogen-induced tumors than normal mice. These

findings lead to the idea that the immune system eliminates cancer cells. Current information about how cancer cells escape this immune surveillance is discussed in Section 25.4.

More and more evidence is mounting that immune-system cells can also have tumorigenic properties. It has been known for a long time that cancers frequently arise at sites of injury or chronic infection. It is estimated that up to 20 percent of cancers are linked to chronic infection. For example, persistent infection of the stomach by the bacterium *Helicobacter pylori* is associated with gastric cancer. Crohn's disease, an inflammatory autoimmune disease that affects the intestines, is associated with colon cancer. Infection with hepatitis B or C viruses increases the risk of a form of liver cancer, hepatocellular carcinoma. Immune-system cells migrate to sites of injury or infection and produce growth factors, thereby stimulating tumor cell proliferation. They also produce factors to induce the growth of blood vessels, which — as we will discuss next — is an essential aspect of tumor growth and dissemination to distant sites.

Tumor Growth Requires Formation of New Blood Vessels

Tumors must recruit new blood vessels in order to grow to a large size. In the absence of a blood supply, a tumor can grow into a mass of about 10^6 cells, roughly a sphere 2 mm in diameter. At this point,

division of cells on the outside of the tumor mass is balanced by death of cells in the center from an inadequate supply of nutrients. Such growth-limited tumors, unless they secrete hormones, cause few problems. However, most tumors induce the formation of new blood vessels that invade the tumor and nourish it, a process called **angiogenesis**. This complex process requires several discrete steps: degradation of the basement membrane that surrounds a nearby capillary, migration of endothelial cells lining the capillary into the tumor, division of these endothelial cells, and formation of a new basement membrane around the newly elongated capillary.

Many tumors produce growth factors that stimulate angiogenesis; other tumors induce surrounding normal cells to synthesize and secrete such factors. Basic fibroblast growth factor (β-FGF), transforming growth factor α (TGF-α), and vascular endothelial growth factor (VEGF), which are secreted by many tumors, all have angiogenic properties. New blood vessels allow the tumor to increase in size and thus increase the probability that additional harmful mutations will occur. The presence of an adjacent blood vessel also facilitates the process of metastasis.

The VEGF receptors, which are tyrosine kinases, regulate several aspects of blood vessel growth, such as endothelial cell survival and growth, endothelial cell migration, and vessel wall permeability. VEGF expression can be induced by oncogenes and by hypoxia. As detailed in Chapter 21, the hypoxia signal is mediated by hypoxia-

inducible factor 1α (HIF-1α), a transcription factor that is activated in low-oxygen conditions and that binds to and induces transcription of the VEGF gene and about 30 other genes, including many enzymes in the glycolytic pathway. An enhancement of glycolysis can in turn stimulate the growth of many cancer cells. HIF-1α activity is controlled by an oxygen sensor composed of a prolyl hydroxylase that is active at normal O_2 levels but inactive when deprived of O_2. Hydroxylation of HIF-1α causes ubiquitinylation and degradation of the transcription factor, a process that is blocked when O_2 is low. Mutations in genes encoding a subunit of the ubiquitin ligase that degrades HIF-1α at ambient oxygen levels trigger certain kidney tumors. Compounds that inhibit angiogenesis have excited much interest as potential therapeutic agents, but their success in the clinic has thus far been limited.

Invasion and Metastasis Are Late Stages of Tumorigenesis

Tumors arise with great frequency, especially in older individuals, but most pose little risk to their host because they are small and localized. We call such tumors **benign**; an example is a wart, a benign skin tumor. The cells composing benign tumors closely resemble and may function like normal cells. The cell-adhesion molecules that hold tissues together keep benign tumor cells, like normal cells, localized to the tissues where they originate. A fibrous

capsule usually delineates the extent of a benign tumor and makes it an easy target for a surgeon. Benign tumors become serious medical problems only if their sheer bulk interferes with normal functions or if they secrete excess amounts of biologically active substances, such as hormones. For example, acromegaly, the overgrowth of head, hands, and feet, can occur when a benign pituitary tumor causes overproduction of growth hormone.

In contrast to benign tumor cells, **malignant** tumor cells are able to invade nearby tissue, spreading and seeding additional tumors while the cells continue to proliferate (Figure 25-5). This ability is a major characteristic that differentiates malignant tumors from benign ones. Some malignant tumors, such as those in the ovary or breast, remain localized and encapsulated, at least for a time. When these tumors progress, however, the cells invade surrounding tissues and form metastases (Figure 25-6a).

FIGURE 25-6 Metastasis. (a) First steps in metastasis, using breast carcinoma cells as an example. Cancer cells leave the main tumor and attack the basement membrane, using extracellular matrix (ECM) fibers to reach the blood vessels. The cancer cells can be attracted by signals such as epidermal growth factor (EGF), which can be secreted by macrophages. At the blood vessels, they penetrate the layer of endothelial cells that forms the vessel walls and enter the bloodstream. (b) Carcinoma cells penetrate the extracellular matrix and blood vessel wall by extending invadopodia (actin-rich protrusions of the plasma

membrane), which produce matrix metalloproteases and other proteases to open up a path.

[Data from H. Yamaguchi, J. Wyckoff, and J. Condeelis, 2005, *Curr. Opin. Cell Biol.* **17**:559.]

Normal cells are restricted to their place in an organ or tissue by cell-cell adhesion and by physical barriers such as the *basement membrane*, which underlies layers of epithelial cells and also surrounds the endothelial cells of blood vessels (see Chapter 20 and Figure 1-26). In contrast, cancer cells have acquired the ability to penetrate basement membranes using a cell protrusion called an *invadopodium* and to migrate to distant sites in the body (Figure 25-6b). A developmental process known as the **epithelial-to-mesenchymal transition** (**EMT**) is thought to play a crucial role during the process of metastasis in some cancers. During normal development, the conversion of epithelial cells into mesenchymal cells is a step in the formation of some organs and tissues. An EMT requires distinct changes in patterns of gene expression and results in fundamental changes in cell morphology, such as loss of cell-cell adhesion, loss of cell polarity, and the acquisition of migratory and invasive properties. During metastasis, the EMT regulatory pathways are thought to be activated at the invasive front of a tumor, producing single migratory cells.

As the basement membrane disintegrates, some tumor cells enter the bloodstream, but fewer than 1 in 10,000 cells that escape the primary tumor survive to colonize another tissue and form a

secondary, metastatic tumor. Much of preventative medicine is currently focused on developing methods to identify the rare tumor cells that circulate in the bloodstream. The ability to capture these *circulating tumor cells* would not only provide a powerful and noninvasive tool for the early detection of cancer, but also their analysis could provide insights into the nature of the disease and inform treatment.

In order to produce metastases, tumor cells must not only enter the bloodstream, but also adhere to the lining of the blood vessel in a new location and migrate through it into the underlying tissue, in a process called *extravasation* (see Chapter 20). In order to seed a metastasis at a distant site, the tumor cells must not only disseminate, but also adapt to a foreign tissue environment. At least initially, metastatic tumor cells may not be well adapted to their new environment, but they are thought to evolve to survive and thrive in a foreign context. Little is known about the molecular pathways that facilitate this adaptation, but mounting evidence suggests that some environments are more conductive to cancer cell colonization than others.

Because metastasis is the most common reason for morbidity associated with cancer, much effort is being put into understanding which tumors will become metastatic and how metastasis occurs. Traditionally, the properties of tumor and normal cells have been assessed using microscopic tools, and the prognosis for many

tumors could be determined, within certain limits, from their histology. However, the appearance of cells alone has limited information content, and better ways to discern the properties of cells are desirable, both to understand tumorigenesis and to arrive at meaningful and accurate decisions about prognosis and therapy. The advent of methods to assess a tumor's patterns of RNA, protein, lipid, and metabolite production is allowing for a more detailed examination of tumor properties. Not surprisingly, primary tumors are often distinguishable from metastatic tumors by the RNAs and proteins that they produce. Analyses of global patterns of gene expression (described in Chapter 6) are now routinely used to predict patient outcomes and to determine the best course of treatment for many types of cancers. They will soon become the standard in determining treatment options. ■

KEY CONCEPTS OF SECTION 25.1

How Tumor Cells Differ from Normal Cells

- The genomes of most cancer cells acquire thousands of mutations and other genetic alterations that include point mutations, deletions, amplifications, chromosomal rearrangements and whole chromosome gains and losses.
- The changes in genetic makeup of cancer cells include oncogenic mutations that affect a wide variety of cellular functions.
- Oncogenic mutations in growth control pathways, cell cycle regulation, and in telomere maintenance are examples of how cancer cells acquire the ability to proliferate indefinitely.
- Cancer cells often exhibit altered metabolism, such as a switch of glucose metabolism to anaerobic glycolysis.
- Cancer cells lose contact inhibition, which allows them to grow in a mass outside the confines of a normal cell layer.

- Tumors are complex organs composed of different cell types that interact with their environment to obtain a maximal growth advantage.
- Tumors require angiogenesis, the formation of new blood vessels, in order to grow to a large mass.
- Cancer cells sometimes invade surrounding tissues, often breaking through the basement membranes that define the boundaries of tissues and spreading through the body to establish secondary areas of growth, a process called *metastasis*.
- Metastatic tumor cells acquire migratory properties in a process called the *epithelial-to-mesenchymal transition*.

25.2 Genetic and Genomic Basis of Cancer

Cancer can be considered to be a genetic disease in two different ways. Considering the mechanism of cancer formation, we know that tumors arise from somatic cells that have acquired a collection of mutations that give them the ability to proliferate when their neighbors cannot. In this sense, somatic mutations are the cause of cancer. When we consider the tumors themselves, we can see that they typically have acquired thousands of point mutations and genomic rearrangements; in this sense, mutations are a consequence of cancer. These contrasting relationships can be reconciled by viewing cancer progression as a form of *Darwinian evolution* acting on the growth of clones of cancer cells with cycles of mutation and selection. In this view, early in the process of cancer formation, the genome of a precancerous cell becomes highly mutable and the cells and its descendants begin to acquire random mutations. Although the vast majority of these mutations are not in genes and have little or no phenotypic effect on the cells that harbor them, a small fraction will have functional consequences. Those mutations that enable the precancerous cells to grow more rapidly, to avoid being eliminated, or to spread through the body will be selected for and will become part of the lineage that forms a tumor. Oncogenic mutations are those that are selected because they are causal drivers of cancer progression. Most modern cancer biology

research aims at identifying oncogenic mutations and understanding their underlying mechanism.

In this section, we first consider the major causes of somatic mutations in cancer — these are environmental DNA-damaging agents known as **carcinogens** and either inherited or somatic mutations that prevent DNA damage from being repaired with high fidelity. We then consider the spectrum of mutations found in cancer genomes which include a small fraction of oncogenic driver mutations. Next we consider the major types of oncogenic mutations that include virus-borne onncogenes, and gain-of-function mutations and loss-of-function mutations in the genome. Finally, we consider oncogenic mutations that exert their effect through general changes in gene expression via chromatin structure or microRNA expression.

Carcinogens Induce Cancer by Damaging DNA

The ability of chemical carcinogens to induce somatic-cell mutations results from the DNA damage they cause as well as the errors introduced into DNA that result from the mechanisms to repair that damage. The strongest evidence that carcinogens act through mutagenesis comes from the observation that there is a strong correlation between the ability of a compound to cause

mutations in DNA of cultured cells and to transform cells and induce cancer in animal models.

Although substances identified as chemical carcinogens have a broad range of chemical structures, they can be classified into two general categories. *Direct-acting carcinogens*, of which there are only a few, are highly reactive compounds that can react with and modify nucleotide bases in DNA so as to distort the normal pattern of base pairing. If the modified nucleotides are not repaired, they allow an incorrect nucleotide to be incorporated during replication. This class of carcinogens includes ethylmethane sulfonate (EMS), dimethyl sulfate (DMS), and nitrogen mustards.

In contrast, *indirect-acting carcinogens* are relatively unreactive compounds that become modified to more reactive forms by cellular *cytochrome P-450 enzymes*. P-450 enzymes normally function to add electrophilic centers, such as OH groups, to nonpolar foreign chemicals in order to solubilize them so that they can be excreted from the body. For some compounds, modification by cytochrome P-450 increases the reactivity of the compound with DNA converting it into a mutagen and a carcinogen.

Some Carcinogens Have Been Linked to Specific Cancers

Since the earliest awareness of cancer as a disease intrinsic to the cells of the body, it became clear that at least some cancers resulted from the action of environmental poisons. As early as the eighteenth century, chimney sweeps' exposure to soot was associated with a high incidence of scrotal cancer, and the use of tobacco as snuff was associated with nasal cancer. Environmental chemicals were originally associated with cancer through experimental studies in animals. The classic test for a carcinogen is to repeatedly paint a test substance on the back of a mouse and look for development of local or systemic tumors in the animal. Such assays led to the purification of a pure chemical carcinogen, benzo(*a*)pyrene, from coal tar in 1933.

Although chemical carcinogens are believed to be risk factors for many human cancers, a direct link to specific cancers has been established in only a few cases, the most important being lung cancer and the other cancers that are associated with smoking (of the larynx, pharynx, stomach, liver, pancreas, bladder, cervix, and more). Epidemiological studies first indicated that cigarette smoking was the major cause of lung cancer. The chemical *benzo(*a*)pyrene*, found in cigarette smoke as well as in coal tar, undergoes metabolic activation by cytochrome P-450 in the lungs (Figure 25-7) to form a potent mutagen that mainly causes conversion of cytosine (C) to adenine (A) bases, a transversion mutation. When applied to cultured bronchial epithelial cells, activated benzo(*a*)pyrene induces transversion mutations at many loci. *Benzo(*a*)pyrene* thus leaves a

specific fingerprint in the DNA of cancer cells from heavy smokers. Cigarette smoke is known to contain more than 60 different carcinogens, and the overall profile of mutations in lung cancer appear as a complex pattern of overlapping signatures.

FIGURE 25-7 Enzymatic processing of benzo*(a)*pyrene to a more potent mutagen and carcinogen. Liver enzymes, particularly P-450 enzymes, modify benzo(*a*)pyrene in a series of reactions, producing 7,8-diol-9,10-epoxide, a highly potent mutagenic species that reacts with DNA primarily at the N_2 atom of a guanine (G) base. The resulting adduct, $(+)\text{-}trans\text{-}anti\text{-}\mathrm{B}(a)\mathrm{P}\text{-}N^2\text{-}\mathrm{dG}$, causes polymerase to insert an A rather than a C opposite the modified G base. The next time the DNA is replicated, a T will be inserted opposite the A, and the mutation will be complete. Horizontal arrows indicate alterations toward greater potency, while vertical arrows indicate changes in the direction of reduced toxicity. The large "O" symbol represents the rest of the multi-ring structure shown in the complete benzo(*a*)pyrene molecule at the left.

In addition to chemical mutagens, electromagnetic radiation of sufficient energy to damage DNA is also carcinogenic. X-rays and gamma rays are of a category of radiation known as ionizing

radiation because they have sufficient energy to strip electrons from atoms, generating ions. When ionizing radiation hits DNA it has sufficient energy to break a strand of DNA. X-rays have been known to cause mutations in *Drosophila* since the classic experiments of Hermann J. Muller were published in 1927. A connection between ionizing radiation and cancer was first indicated by the high incidence of cancer in the mouths of "radium girls" who worked in watch factories and ingested radium from licking the paintbrushes used to paint luminous dials. A causal relationship was solidified from a large-scale study from atomic bomb survivors who were shown to have an increased incidence of cancer, principally leukemia, in proportion to their exposure to radiation from the bomb blast. Because the repair of DNA breaks is often error prone, ionizing radiation causes a very broad spectrum of mutations.

UV light does not have the energy to break DNA strands but can interact with adjacent pyrimidine residues to create chemically altered DNA that is repaired by the nucleotide excision repair pathway (see Figure 5-18). The predominant signature of melanoma, a cancer caused by exposure to sunlight, is a preponderance of cytosine (C) to thymine (T) bases conversions, consistent with the known mutagenic effect of UV light.

Familial Syndromes That Cause Loss of DNA Repair Can Lead to Cancer

Even without exposure to any external carcinogens or mutagens, normal biological processes generate a large amount of DNA damage. That damage is due to depurination reactions, to alkylation reactions, and to the generation of reactive species such as oxygen radicals, all of which alter DNA. It has been estimated that in every cell, more than 20,000 alterations to the DNA occur each day from reactive oxygen species and depurination. The vast majority of this damage is correctly repaired by the high-fidelity DNA-repair systems that are described in Chapter 5. As we will see, the large number of mutations found in most cancers results from defects in one or more of these repair systems.

One well-recognized way for DNA repair to fail is by familial inheritance of a defect in one of the DNA-repair pathways. Table 25-1 shows the best understood familial syndromes that result from defects in DNA-repair pathways and their corresponding effects on an increase in the propensity to develop cancer. For example, people who inherit the disease xeroderma pigmentosum (XP) have a 1000-fold increase in the propensity to develop skin cancer. Seven of the eight known XP genes have been identified as components of the nucleotide excision-repair machinery, and the connection to skin cancer is clear since repair of DNA damage caused by UV light primarily requires nucleotide excision repair. Hereditary nonpolyposis colorectal cancer (HNPCC, also known as *Lynch syndrome*) causes a greatly increased propensity to develop colon cancers. HNPCC genes encode components of the mismatch-repair

system; in the absence of mismatch repair, colon cancer progresses from benign polyps to full-fledged tumors much more rapidly than usual, presumably because the precancerous cells acquire oncogenic mutations at an increased rate. Defects in mismatch repair should in theory increase the probability of oncogenic mutations in all cells in the body. The specificity of HNPCC for colon cancer is not well understood.

TABLE 25-1 • Some Human Hereditary Diseases and Cancers Associated with DNA-Repair Defects

Disease	DNA-Repair System Affected	Sensitivity	Cancer Susceptibility	Symptoms
Hereditary nonpolyposis colorectal cancer	DNA mismatch repair	UV irradiation, chemical mutagens	Colon, ovary	Early development of tumors
Xeroderma pigmentosum	Nucleotide excision repair	UV irradiation, point mutations	Skin carcinomas, melanomas	Skin and eye photosensitivity, keratoses
Bloom's syndrome	Repair of double-strand breaks by homologous recombination	Mild alkylating agents	Carcinomas, leukemias, lymphomas	Photosensitivity, facial telangiectases, chromosome alterations
Fanconi anemia	Repair of double-strand	DNA cross-linking	Acute myeloid leukemia,	Developmental abnormalities

	breaks by homologous recombination	agents, reactive oxidant chemicals	squamous-cell carcinomas	including infertility and deformities of the skeleton, anemia
Hereditary breast cancer, BRCA1 and BRCA2 deficiency	Repair of double-strand breaks by homologous recombination		Breast and ovarian cancer	Breast and ovarian cancer

SOURCE: Modified from A. Kornberg and T. Baker, 1992, *DNA Replication*, 2d ed., W. H. Freeman and Company, p. 788; J. H. J. Hoeijmakers, 2001, *Nature* **411**:366; and L. H. Thompson and D. Schild, 2002, *Mutat. Res.* **509**:49.

Double-strand breaks are particularly severe lesions because incorrect rejoining of double strands of DNA can lead to gross chromosomal rearrangements and translocations, such as those that produce a hybrid gene or bring a growth regulatory gene under the control of a different promoter or enhancer. Often the repair of such damage depends on using the homologous chromosome as a template (see Figure 5-21). The B and T cells of the immune system are particularly susceptible to DNA rearrangements caused by double-strand breaks created during rearrangement of their immunoglobulin or T-cell receptor genes, which explains the frequent involvement of these loci in leukemias and lymphomas. *BRCA1* and *BRCA2*, genes implicated in human breast and ovarian cancers, encode important components of DNA-break repair systems. As we saw in Chapter 5, broken DNA ends can normally be

repaired by recombination with the homologous chromosome, which is usually a high-fidelity process, returning the broken chromosome to the wild-type sequence. However, if homologous recombination fails, the broken ends can be repaired by nonhomologous end joining (NHEJ), which is highly mutagenic. Cells lacking either of the BRCA functions are unable to repair broken DNA strands by homologous recombination and they have no alternative but to repair by NHEJ, which introduces an insertion, a deletion, or a chromosome rearrangement at the site of the break.

Somatic Mutations in the DNA Damage Response Pathway Are Oncogenic

Inherited predispositions for a defect in DNA repair account for only a small fraction of tumors, yet the vast majority of cancer cells exhibit a much greater propensity for genome instability and a higher rate of mutagenesis than normal somatic cells. This propensity of cancer cells to acquire new mutations at a high rate is the result of somatic mutations acquired during cancer progression that compromise efficient DNA repair. The majority of these repair-defective somatic mutations do not directly affect the repair pathways themselves but alter the ways that cells respond to DNA damage.

We saw in Chapter 19 that a general response to DNA damage of all dividing eukaryotic cells is to arrest the cell cycle to give the repair systems time to repair the damage before entry into mitosis. In brief outline, serine kinases ATM or ATR are recruited to sites of DNA damage and become activated (Figure 19-34). The activated kinases then signal the presence of DNA damage by phosphorylating p53 on a serine residue in the N-terminus of the protein. This phosphorylation causes the protein to evade ubiquitin-mediated degradation, leading to a marked stabilization of p53 that activates transcription of the gene encoding p21, which in turn binds to and inhibits mammalian CDK2, CDK1, and CDK4/6 complexes (Figure 19-34). The net outcome of this signaling process is for cells with damaged DNA to activate cell cycle checkpoints causing an arrest in the cell cycle, allowing time for DNA repair to be completed before chromosome segregation in mitosis. Once DNA repair has been completed, p53 is degraded and the cell cycle will recommence to complete mitosis. If for some reason the DNA damage cannot be repaired, the cell will be arrested permanently and become senescent.

This pathway that enables DNA-repair enzymes to operate effectively appears to be the aspect of DNA repair that is most vulnerable to somatic mutation. Most, if not all, human tumors have mutations either in p53 itself or in other proteins that regulate p53 activity. When the p53, G_1, and S phase checkpoint control does not operate properly, damaged DNA can replicate, generating mutations

and DNA rearrangements that are passed on to daughter cells and make their transformation into metastatic cells more likely. For example, loss of p53 function leads to a hundredfold or greater increase in the frequency of gene amplification. At the same time, loss of p53 function limits the duration of G_2 arrest, allowing cells with damaged DNA to enter mitosis prematurely. The activity of p53 is not limited to inducing cell cycle arrest, and in Section 25.4 we will describe the role of p53 in inducing apoptosis.

The fact that cancer cells usually contain one or more defective DNA-repair systems provides an Achilles heel that allows tumors to be killed by chemicals that intentionally damage DNA. For example, traditional anticancer chemotherapeutic agents like cis-platinum cause DNA cross-links that tumor cells cannot efficiently repair, while drugs like doxorubicin and etoposide, which inhibit DNA topoisomerases, cause large numbers of DNA breaks during S phase, blocking entry into mitosis and resulting in tumor cell death. This loss of normal DNA repair, combined with the rapid proliferation of tumor cells, explains why commonly used chemotherapy drugs preferentially kill cancer cells, but do not kill the normal nonproliferating cells in the body. An exception to this are the rapidly proliferating normal cells in the bone marrow and immune system, which are also damaged to some extent by these drugs. This explains why cancer patients develop anemia and are susceptible to infections during chemotherapy treatment. ■

Cancer Genome Sequencing Reveals an Enormous Diversity of Somatic Mutations

The advent of next-generation DNA-sequencing technology has enabled rapid sequencing of thousands of cancer genomes and compilation of the vast array of somatic mutations in cancer cells. The large collection of cancer genome sequences shown in Figure 25-8 shows the complexity and variation in the types and numbers of different somatic mutations found in tumors. Normal somatic cells acquire an average of about one mutation per cell division. Given the total accumulation of $>10^5$ mutations in cancer cells, the mutation rate during cancer progression is at least 1000 times greater than normal. Despite the enormous diversity of somatic mutations in cancer, a number of useful generalizations can be made.

FIGURE 25-8 Sequenced cancer genomes carry a large number and wide variety of somatic mutations. A compendium of 2658 cancer genome sequences compared to matching normal somatic cells. The sequences are grouped into 38 tumor types and each dot specifies the number of mutations in a single tumor categorized as single nucleotide variants (SNVs), short insertions or deletions (Indels), or structural variants (SVs).

[P. J. Campbell et al., 2020, "Pan-Cancer Analysis of Whole Genomes," *Nature* **578**:82–93, https://doi.org/10.1038/s41586-020-1969-6, (Creative Commons Attribution 4.0 International License).]

1. Somatic mutations can be grouped into three general types: *s*ingle *n*ucleotide *v*ariants (SNVs, or point mutations); *in*sertions or *del*etions (Indels); or *s*tructural *v*ariants (SVs), which include chromosomal rearrangements, duplications, and copy number variations.

2. Although a typical tumor might contain 5000 SNVs, 500 Indels, and 50 SVs, there is enormous variation in number from one tumor to another even for the same type of cancer.
3. The cancers that have the greatest number and variation in mutations arise from tissues that have been exposed to mutagens: melanoma from sunlight and lung tumors from heavy smokers.
4. The types of mutations can reflect the underlying mechanism for increased mutagenesis. For example, breast tumors from women carrying a BRCA1 mutation tend to have a greater proportion of Indels and SVs than sporadic breast tumors. This is consistent with the expectation that a BRCA1 defect would lead to error-prone repair of DNA breaks, leading to Indels and SVs.

Oncogenes Were Discovered by Their Association with Tumor Viruses

Now that we have seen some of the ways that cancer cells acquire a large number of random somatic mutations, we turn to the problem of identifying the small fraction of these mutations that have functional consequences and have contributed to cancer progression. With the modern capability of analyzing entire genomes, we now know that a typical tumor may have approximately five known *driver mutations* that contribute to the uncontrolled cell proliferation, avoidance of programmed cell

death, and unstable genome that are hallmarks of cancer cells. Finding a few driver mutations among tens of thousands of somatic mutations has only been possible recently; the first known genetic drivers of oncogenesis were revealed in cases in which a single powerful driver was activated through an unusual genetic event. The genes that caused the oncogenic **transformation** are known as **oncogenes**.

Pioneering studies by Peyton Rous beginning in 1911 led to the initial recognition that a virus could cause cancer when injected into a suitable host animal. Many years later, molecular biologists showed that his Rous sarcoma virus (RSV) is a **retrovirus** whose RNA genome is reverse-transcribed into DNA, which is then incorporated into the host-cell genome (see Figure 5-44). In addition to the normal genes present in all retroviruses, oncogenic transforming viruses such as RSV contain an oncogene — in the case of RSV, the v-*src* gene. Subsequent studies with mutant forms of RSV demonstrated that only the v-*src* gene, not the other viral genes, was required for cancer induction.

In the late 1970s, scientists were surprised to find that normal cells from chickens and other species contain a gene that is closely related to the RSV v-*src* gene. This normal cellular gene, a **proto-oncogene**, is commonly distinguished from the viral gene by the prefix *c* for "cellular" (c-*SRC*). The product of this gene, c-Src, is a cytosolic protein tyrosine kinase which participates in many signal

transduction pathways. RSV and other oncogenic transforming viruses are thought to have arisen by incorporating a normal host cellular proto-oncogene into their genome. Subsequent mutations in the incorporated gene then converted it into a dominantly acting oncogene, encoding a constitutively active kinase that is able to transform host cells even in the presence of the normal c-*SRC* proto-oncogene. When this phenomenon was first discovered, it was startling to find that these dangerous viruses were turning the hosts' own genes against them.

In other cases, retroviruses can cause cancer not by carrying an oncogene but by integrating into the host-cell DNA near a cellular proto-oncogene and activating its expression. For example, in the cells from tumors caused by avian leukosis virus (ALV), the retroviral DNA is inserted near the *MYC* gene. These cells overproduce MYC protein, which causes abnormally rapid proliferation of cells, initiating the cancer progression. Additional subsequent mutations have to occur before a full-fledged tumor becomes evident.

Single Oncogenic Drivers Can Be Activated by Chromosome Rearrangements

In the 1960s, researchers first realized that some cancers harbor characteristic chromosome rearrangements that could be detected by light microscopy. Chronic myelogenous leukemia (CML), a common leukemia in humans, was found to be associated with the **Philadelphia chromosome** (Figure 25-9a), which is generated by a translocation between chromosomes 22 and 9. The two chromosomes exchange their terminal regions, which leads to a characteristic alteration in the size of chromosome 22. Subsequent cloning and analysis of the DNA at the breakpoint of this translocation showed that a new fusion protein, called BCR-ABL, is generated. This hybrid protein kinase phosphorylates proteins that the wild-type ABL kinase normally does not phosphorylate, thereby inappropriately activating many intracellular signal-transducing proteins. If this translocation occurs in a hematopoietic cell in the bone marrow, the activity of the chimeric *BCR-ABL* oncogene results in the initial phase of CML, characterized by an expansion in the number of white blood cells.

FIGURE 25-9 BCR-ABL protein kinase. (a) Origin of the Philadelphia chromosome from a translocation of the tips of chromosomes 9 and 22 and the oncogenic fusion protein formed by that translocation. (b) The BCR-ABL fusion protein is a constitutively active kinase that phosphorylates multiple signal-transducing proteins. Imatinib binds near the active site of BCR-ABL and stabilizes the inactive form that lacks kinase activity. (c) Imatinib bound to the BCR-ABL active site.

[Data from B. Nagar et al., 2002, *Cancer Res.* **62**:4236, PDB ID 1iep.]

The discovery of the Philadelphia chromosome and the critical oncogene it creates, BCR-ABL, combined with the discovery of the molecular action of the ABL protein, together have led to a powerful new therapy for CML. After a painstaking screening of compounds that can inhibit the enzymatic activity of ABL kinase, a highly specific inhibitor named *imatinib* (Gleevec) was identified as a possible treatment for CML. Imatinib, which binds directly to the

active site of the ABL kinase and holds it in an inactive conformation to inhibit its kinase activity, is lethal to CML cells while sparing normal cells (see Figure 25-9b, c). After clinical trials showing that imatinib is remarkably effective in treating CML despite some side effects, it was approved by the FDA in 2001 as the first cancer drug targeted to a signal-transducing protein unique to tumor cells. Imatinib inhibits several other tyrosine kinases that are implicated in different cancers and has been successful in trials for treating those diseases, including forms of gastrointestinal tumors, as well. There are 90 functional protein tyrosine kinases encoded in the human genome, and drugs that inhibit several of these are proving useful in treating other types of cancers.

The development of imatinib represents one of the great successes of an approach to cancer therapy known as *targeted therapy*. In its general outline, the idea behind targeted therapy is to find the oncogenic drivers for a particular type of cancer and then to design a drug that reverses the effect of the oncogenic mutation. The case of targeting BCR-ABL that is the oncogenic driver of CML demonstrates both the power of this method and also reveals its limitations. CML is unusual in that it forms as the result of a single oncogenic driver whose effect can be reversed to cure the disease. As we will see, the majority of cancers result from multiple driver mutations; reversing the effect of any one of them would not cure the disease. In addition, we have seen that most cancers have a high mutation rate and thus would rapidly acquire mutations that confer

resistance to a specific enzyme inhibitor. Indeed, CML tumors eventually acquire mutations in the gene encoding the BCR-ABL fusion protein that prevent binding of imatinib. Researchers have identified molecules that specifically inhibit some of these mutant BCR-ABL kinases; these are used as a second-line therapy for CML. The twin challenges of multiple pathways affected and generation of drug resistance through mutation are features of the underlying genetic complexity of most cancers and remain the most significant obstacles to development of targeted therapies.

Inherited Predisposition for Cancer Enabled Identification of Some Oncogenic Drivers

Another way that individual genes responsible for driving progression were identified was through genetic analysis of syndromes that have a hereditary predisposition to certain cancers. For most of these syndromes, individuals inherit from a parent a loss of function mutation in one allele of the gene; then a somatic mutation of the second allele of the gene initiates cancer progression. A classic inherited cancer syndrome is retinoblastoma, which is caused by loss of function of *RB*. As discussed in Chapter 19, the protein encoded by *RB* regulates cell cycle entry.

Children with hereditary retinoblastoma inherit one defective copy of the *RB* gene, sometimes seen as a small deletion on one of the two copies of chromosome 13. These children develop multiple retinal tumors early in life and generally in both eyes. The loss or inactivation of the normal *RB* gene on the other chromosome is an essential step in tumor formation, giving rise to a cell that produces no functional **Rb protein** (Figure 25-10a). Individuals with sporadic retinoblastoma, in contrast, inherit two normal *RB* alleles, each of which has undergone a loss-of-function somatic mutation in a single retinal cell (Figure 25-10b). Because losing both copies of the *RB* gene in a somatic cell is far less likely than losing one, sporadic retinoblastoma in individuals with two normal copies of the *RB* gene is very rare and usually affects only one eye.

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

FIGURE 25-10 Role of spontaneous somatic mutation in retinoblastoma. This disease is marked by retinal tumors that arise from cells carrying two mutant RB^- alleles. (a) In hereditary (familial) retinoblastoma, a child inherits a normal RB^+ allele from one parent and a mutant RB^- allele from the other parent. When the second normal allele is lost in a heterozygous somatic retinal cell, a cell is generated that lacks any *RB* gene function. (b) In sporadic retinoblastoma, a child inherits two normal RB^+ alleles. Two separate *RB* loss events must occur in a particular retinal cell to produce a cell lacking all *RB* function.

If retinal tumors are removed before they become malignant, children with hereditary retinoblastoma often survive until adulthood and produce children, but they are at an increased risk of

developing other types of tumors later in life. Because their germ cells contain one normal and one mutant *RB* allele, these individuals will, on average, pass on the mutant allele to half their children and the normal allele to the other half. Children who inherit the normal allele are normal if their other parent has two normal *RB* alleles. However, those who inherit the mutant allele have the same enhanced predisposition to develop retinal tumors as their affected parent, even though they inherit a normal *RB* allele from their other, normal parent. Thus the tendency to develop retinoblastoma is inherited as a dominant trait: one mutant copy is sufficient to predispose a person to develop the cancer.

As we will see, many human tumors (not just retinal tumors) contain mutant *RB* alleles or mutations affecting other components of the *RB* pathway; most of these tumors arise as the result of somatic mutations. Although hereditary retinoblastoma cases number about 100 per year in the United States, about 100,000 other cancer cases each year involve *RB* mutations acquired in somatic cells.

Estimates vary, but hereditary cancers (cancers that arise due in part to an inherited version of a gene) are thought to constitute about 10 percent of human cancers. Further work tracing the contributions of human genes seems likely to increase the percentage. It is important to remember, however, that the inherited germ-line mutation alone is not sufficient to cause tumor development. Not only must the inherited normal allele be lost or inactivated, but also

mutations affecting other genes must occur for cancer to develop. Thus a person with a recessive tumor suppressor gene mutation can be exceptionally susceptible to environmental mutagens, such as radiation.

Mutation in only one copy of a tumor suppressor gene itself typically does not cause cancer because the remaining normal allele prevents aberrant growth. However, the subsequent loss or inactivation of the remaining normal allele in a somatic cell, referred to as **loss of heterozygosity (LOH)** causes cancer to develop. Three mechanisms exist that can cause the loss of the normal allele. First, the normal allele can become inactive due to a de novo inactivating mutation or deletion. Second, chromosome missegregation can cause loss of the chromosome carrying the normal allele. Neither mechanism is particularly common. By far the most frequent mechanism for LOH is mitotic recombination between a chromatid bearing the normal allele and a homologous chromatid bearing a mutant allele. Subsequent chromosome segregation can generate a daughter cell that is homozygous for the mutant tumor-suppressor allele.

Oncogenic Driver Mutations Have Been Identified in Many Genes

After discovery of the first oncogenes carried by tumor viruses, in the ensuing 40 years dozens of different genes that can carry oncogenic driver mutations have been identified. These genes were typically identified by studying the unique genetic markers of a particular tumor sample or transformed cell line. The greatest advances have come from studying tumor types, like pediatric cancers and rare types of adult cancer, where the total number of genetic changes is small. Most oncogenic drivers were first identified by one of the following six approaches (we have already seen examples of the first five):

1. Identification of an oncogene associated with a tumor-causing virus.
2. Identification of a gene activated to cause cancer by insertion of a retrovirus.
3. Identification of a gene at the breakpoint in a chromosome rearrangement associated with cancer.
4. Mapping of a gene that causes a familial predisposition to cancer.
5. Identification of a gene that, when activated or up-regulated, can cause cell transformation.
6. Identification of a gene specifically up-regulated in cancer cells.

Oncogenic Driver Mutations Can Be Identified by Comparing Cancer Genomes

All of the oncogenic driver mutations in a given tumor should be discoverable by comparing the genomic sequence of the tumor with that of the sequence of a normal tissue-matched somatic cell. The difficulty with this approach is that for most tumors, out of tens of thousands of somatic mutations only a few will be oncogenic driver mutations. However, when a large number of different cancer genome sequences are compared, patterns emerge that allow driver mutations to be identified among the much larger number of adventitious somatic mutations in tumor cells. The most obvious pattern would be to look for mutations in the same gene appearing across multiple tumors of the same type. This method is based on the concept that cancer cells of the same type have similar morphology, metabolism, and regulatory and gene expression networks and therefore are likely to be the result of similar sets of oncogenic driver mutations. More sophisticated analysis of the sequence information will identify common mutations of the same type across tumors. For example, mutations in *RB* tend to be deletions that cause a loss of gene function, whereas mutations in *Ras* are usually point mutations that have a gain of function.

This type of analysis, applied to 2500 different tumor sequences from different types of cancer, yields a set of common oncogenic drivers shown in Figure 25-11. The average number of oncogenic driver mutations found in these tumors was five and the most common driver gene mutated is p53 (*TP53*), which was found in 77 percent of the tumors. Although at first inspection the number and

variety of oncogenic drivers can be bewildering, almost all of these genes had previously been associated with cancer progression and their basic cellular functions are known. Moreover, many of the oncogenic driver genes operate in a relatively small number of regulatory pathways and cellular processes, as shown in Table 25-2. In Section 25.3, we describe in greater detail the function of oncogenic drivers that participate in cell growth control pathways; in Section 25.4, we consider oncogenic drivers that prevent programmed cell death and allow evasion of immune surveillance.

FIGURE 25-11 Oncogenic driver mutations identified in sequenced cancer genomes. A compendium of 2583 cancer genome sequences from 26 different tumor types were searched for shared oncogenic driver mutations. The columns of the table represent

different types of cancer and the rows represent the most prevalent driver mutations in order of frequency. The numbers in the table represent the number of tumors of a given type found with a given driver mutation. The colored bars represent the proportion of driver mutations of a given type. The most common types of mutations are single nucleotide variants in the coding sequence (yellow), which can be either loss-of-function mutations as in the case of TP53 or gain-of-function mutations as in the case of KRAS. Common loss-of-function mutations are structural variants which lead to a deleted or truncated gene (red) and less common intron splicing mutants (light red). Common gain-of-functions mutations are structural variants that lead to an amplified gene or a gene fusion (green) and less commonly promoter mutations (light green). Tumor suppressor genes (labeled red) predominantly carry loss-of function oncogenic driver mutations, whereas oncogenes (labeled green) carry gain-of function oncogenic driver mutations.

[Data from ICGC/TCGA Pan-Cancer Analysis of Whole Genomes Consortium, 2020, *Nature* **258**:82.]

Oncogenic Drivers Can Be Gain-of-Function or Loss-of-Function Mutations

In the simplest terms, gene function can be altered by a mutation in one of two ways. A gene can be partially or completely inactivated by a mutation to cause a loss of function, or a gene can possibly acquire from a mutation increased activity or a new activity that could be considered a gain of function. It is usually possible to deduce from a cancer genome sequence, whether an oncogenic mutation causes a loss of function or a gain of function and thus to obtain important information about the mechanism by which the mutation drives cancer progression.

Typical loss-of-function mutations:

1. A *deletion* of all or part of a gene.
2. A *point mutation* in the coding sequence that introduce a stop codon or a frameshift.

Typical gain-of-function mutations:

1. *Duplication or amplification* of the gene leading to overproduction of the encoded protein.
2. A *point mutation* that results in a hyperactive or constitutively active protein product.
3. A *promoter mutation* that results in increased expression of the protein product.
4. A DNA rearrangement that places the gene under the control of an enhancer or promoter that results in increased or inappropriate expression of the protein product.

Genes for which the oncogenic forms arise because of a loss-of-function mutation are usually known as **tumor suppressor genes**. *RB* is the prototypical tumor suppressor gene and we have already seen that retinoblastoma arises because of loss-of-function mutations in both copies of the *RB* gene. We could also deduce that *RB* was a tumor suppressor gene from the cancer genome sequences in Figure 25-11, since most of the oncogenic mutations in *RB* are deletions. Similarly, it is evident that p53 is a tumor

suppressor gene since about half of the oncogenic mutations in the *TP53* gene are deletions.

Genes for which the oncogenic forms arise because of a gain-of-function mutation are usually known as oncogenes. For example, the oncogenic mutation in the *RAS* gene is due to a single base change that permanently activates the Ras protein in the active GTP-bound state and inappropriately activates the MAP kinase pathway, generating an excessive or uncontrolled proliferation-promoting signal. Almost all of the *RAS* mutations identified in tumors are of this type. In contrast, the *MYC* oncogene typically acquires a gain of function by amplification of the *MYC* gene, which increases the abundance of the protein product.

Tumor Suppressor Genes and Oncogenes Often Operate in the Same Pathway

Most of the common oncogenic mutations shown in Figure 25-11 affect pathways that regulate growth control or cell cycle progression. These pathways contain some elements that act positively, but they usually contain negatively acting elements as well (Figure 25-12). For pathways that promote cell growth and cancer progression, gain-of-function oncogenic mutations can occur in pathway elements that act positively, whereas loss-of-

function mutations may occur in pathway elements that act negatively. Thus both oncogenes and tumor suppressor genes can be found that function in the same pathway. However, most tumors usually have only one oncogenic mutation that activates a given pathway. For example, many tumors have oncogenic mutations in *Ras* or *Raf* (see Figure 25-11), but very few have mutations in both genes since these proteins operate in the same signal transduction pathway (see Figure 16-13 and Table 25-2).

FIGURE 25-12 A typical cell growth pathway showing how gain-of-function or loss-of-function mutations in the same pathway can drive cancer progression. A typical pathway is shown that activates cell proliferation by gene transcription and initiation of cell cycle progression in response to an extracellular mitogenic signal. If proteins that act positively in this pathway, such as the receptor protein or an intracellular signaling protein, can become oncogenes by acquiring a gain-of-function mutation. In contrast, a negative

regulator of the pathway may activate the pathway because of a loss-of-function mutation. In such a case the corresponding gene for the negative regulator would be a tumor suppressor gene.

TABLE 25-2 • Common Types of Mutations That Drive Cancer Progression

Cellular Process	Protein (Human Gene)	Type of Mutation (Gain of Function or Loss of Function)
Activation of a mitogenic growth pathway (e.g., the MAP kinase pathway)	Ras (*KRAS*)	Activating coding (GoF)
	Raf (*BRAF*)	Activating coding and promoter (GoF)
	Nf1 (*NF1*)	Mostly deletion (LoF)
Inactivation of a growth inhibitory pathway (e.g., TGFβ pathway)	Smad4 (*SMAD4*)	Mostly deletion (LoF)
Activation of cell cycle initiation	p16 (*CDKN2A*)	Mostly deletion (LoF)
	Rb (*RB*)	Mostly deletion (LoF)
	Cyclin D (*CCND1*)	Gene amplification (GoF)
Sustaining chromosome replication by elongation of telomeres	Telomerase (*TERT*)	Promoter (GoF)
Loss of DNA damage checkpoint	p53 (*TP53*)	Deletion and coding (LoF)
	ATM (*ATM*)	Deletion and coding (LoF)

Avoidance of apoptosis	p53 (*TP53*)	Deletion and coding (LoF)
	Bcl2 (*MCL1*)	Gene amplification (GoF)
	PI-3 kinase (*PIK3CA*)	Activating coding (GoF)
	PTEN (*PTEN*)	Mostly deletion (LoF)
Change in chromatin state by SWI/SNF	ARID1 (*ARID1A*)	Mostly deletion (LoF)
Activation of nuclear transcription factors	MYC (*MYC*)	Gene amplification (GoF)
	β-catenin (*CTNNB1*)	Activating coding (GoF)

MicroRNAs Can Promote and Inhibit Tumorigenesis

In the last two decades, a new class of oncogenic factors has emerged. Noncoding RNAs (RNAs that do not encode proteins), especially microRNAs (miRNAs), play a critical role in tumorigenesis. As discussed in Chapter 9, generation of miRNAs typically involves the transcription of a precursor RNA that, through a number of processing steps, is trimmed down to a mature miRNA that is 20–22 nucleotides long. The mature miRNA usually base-pairs with the 3′ untranslated region (UTR) of its target RNA and inhibits

its translation or sometimes causes its degradation (Chapter 9). To date, more than 1500 miRNAs have been identified in humans and have been implicated in the regulation of as many as 30 percent of the cell's mRNAs, with fundamental roles in cell proliferation, differentiation, and apoptosis. A number of miRNAs have also been shown to function as tumor suppressor genes or oncogenes.

The first known role for miRNAs in tumorigenesis was revealed by the analysis of chromosomal region 13q14.3. This genomic region is found deleted in most cases of chronic lymphocytic leukemia (CLL), prostate cancer, and pituitary adenomas. Characterization of the disease-causing deletion showed the absence of two distinct miRNAs encoded in the deleted region. Deletions of the homologous miRNAs in a mouse strain caused the mice to develop CLL, showing that these miRNAs act as tumor suppressors. The two miRNAs appear to repress translation of certain cell proliferation proteins; in the absence, proliferation of B cells is increased. Similarly, the *let-7* family of miRNAs has been implicated in lung, colon, breast, and ovarian cancer. Let-7 miRNAs repress the translation of Ras mRNA. Thus in the absence of the miRNAs, Ras is constitutively overproduced, contributing to tumorigenesis. Let-7 miRNAs have other targets as well, such as the oncogenic transcription factor MYC, which we will discuss in detail in the next section. A general theme that emerges in the study of miRNAs in cancer is that each miRNA has multiple targets and therefore ample opportunities to contribute to tumorigenesis.

Other miRNAs have also been found to be overexpressed in cancer. Of particular interest is miR-21, which is overexpressed in most solid tumors, including glioblastomas and breast, lung, pancreatic, and colon tumors. This miRNA targets several tumor suppressor genes, among them the gene encoding the PTEN phosphatase, which normally inhibits the PI-3 kinase signal transduction pathway (Chapter 16). Much more needs to be learned about how miRNAs contribute to tumorigenesis, but it is clear that through their ability to regulate many different genes, they can influence disease progression in more than one way.

Epigenetic Changes Can Contribute to Tumorigenesis

We have just seen how mutations can be oncogenic by causing a loss of function of a tumor suppressor gene or a gain of function in an oncogene. As we saw in Chapter 9, gene expression can either decrease or increase according to the chromatin state. Genes with global effects on chromatin state through changes in DNA methylation, as well as changes in the activity of *histone-modifying enzymes* or *chromatin-remodeling complexes*, are now recognized as major drivers of tumorigenesis.

DNA methylation occurs at cytosines of CpG islands, which are found largely in promoters of genes. Methylation of these Cs leads to

repression of the promoters. A large fraction of colorectal cancers are characterized by DNA hypermethylation. DNA hypomethylation is also a hallmark of cancer. The promoters of many genes involved in cancer are hypomethylated, and expression of the genes under their control is therefore increased. For example, 25 percent of acute myeloid leukemias are characterized by DNA hypomethylation that is due to inactivating mutations in an enzyme that catalyzes the methylation of CpG dinucleotides.

Genes encoding chromatin modifiers and regulators have also emerged as drivers of tumorigenesis. Systematic, whole genome sequencing of many tumor types has revealed highly recurrent alterations in approximately 40 genes encoding epigenetic regulators. Recurrent mutations were found in genes encoding enzymes that modify histones or proteins that bind to these post-translational modifications of histones. Genes encoding histone methyl transferases, histone demethylases, and histone acetyl transferases have all been found mutated in a wide variety of tumors. Interestingly, tumors typically harbor only a single mutated allele of a gene encoding a chromatin-modifying enzyme, indicating that these mutations are haplo-insufficient. Presumably, losing both alleles would kill the cell, but having only one functional allele alters the extent of histone modification and thus the expression of target genes sufficiently to promote tumorigenesis.

Central among the chromatin-remodeling factors implicated in cancer are the SWI/SNF complexes. These large and diverse

multiprotein complexes, which have an ATP-dependent helicase at their core, often control histone modification and chromatin remodeling (see Chapter 8). For example, they can cause changes in the positions or structures of nucleosomes, making genes accessible or inaccessible to DNA-binding proteins that control transcription. If a target gene is normally activated or repressed by SWI/SNF-mediated chromatin changes, mutations in the genes encoding SWI or SNF proteins will cause changes in the expression of that gene. Studies with transgenic mice suggest that SWI/SNF normally plays a role in repressing the expression of *E2F* genes, thereby inhibiting progression through the cell cycle. Thus loss of SWI/SNF function can lead to overgrowth and perhaps cancer.

Recent evidence from humans and mice has strongly implicated the *SNF5* gene in cancer. The SNF5 protein is a core member of the SWI/SNF complex. In humans, inactivating somatic *SNF5* mutations cause rhabdoid tumors, which most commonly form in the kidney, and an inherited (familial) disposition to form brain and other tumors. Subsequent studies have found genes encoding various BAF proteins, which are also subunits of the SWI/SNF complex, to be mutated in 40 percent of renal cancers, 50 percent of ovarian cancers, and a high fraction of liver and bladder cancers. In summary, epigenetic misregulation has emerged as a major contributor to tumorigenesis. In hindsight, this notion is probably not surprising, given that epigenetic regulation offers the

opportunity to change the expression of many factors and regulatory pathways simultaneously.

KEY CONCEPTS OF SECTION 25.2

Genetic and Genomic Basis of Cancer

- Oncogenic mutations can result from DNA-copying errors or through the effect of environmental mutagens such as DNA-alkylating agents, UV light, and ionizing radiation.
- Mutagens that can cause cancer are known as carcinogens. Some carcinogens such as benzo(*a*)pyrene must first be activated by cytochrome P-450 enzymes.
- A major driver of mutagenesis in cancer cells is through the loss of normal DNA-repair processes. Inherited defects in DNA-repair processes, such as mutations in the *BRCA1* gene, are associated with an increased susceptibility for certain cancers.
- The most common somatic mutations that increase mutagenesis in cancer cells cause loss of the DNA damage checkpoint. Most such mutations are in the tumor suppressor gene *p53*.
- Sequencing of cancer genomes typically reveals thousands of mutations, which include single nucleotide variants (SNVs), insertions or deletions (Indels), or structural variants (SVs) that include chromosomal rearrangements, duplications, and copy-number variations.
- The first cancer-causing oncogenes were identified by their association with tumor viruses.
- Cellular oncogenic driver mutations have been identified at the break points of chromosome rearrangements, by mapping genes responsible for familial cancer syndromes, and by assays for transformation of tissue-culture cells.
- The first tumor suppressor gene to be identified, *RB*, is mutated in retinoblastoma and many other tumors. Inheritance of a single mutant allele of *RB* greatly increases the probability that a cancer will develop, because a somatic cell readily lose the functional copy of *RB* by loss of heterozygosity (LOH) by mutation or deletion of the normal allele, chromosome mis-segregation, or mitotic recombination.
- Comparison of large numbers of genome sequences from the same tumor type allows oncogenic driver mutations to be distinguished from the many adventitious mutations present in cancer genomes.
- Many oncogenic driver genes cause cell proliferation by activating growth-promoting pathways or by inhibiting growth-inhibiting and apoptotic pathways.

- A gene that becomes an oncogenic driver as a result of a gain-of-function mutation is known as an *oncogene*.
- A gene that becomes an oncogenic driver as a result of a loss-of-function mutation is known as a *tumor suppressor gene*.
- Micro-RNAs (miRNAs) can promote or inhibit tumorigenesis by affecting the expression of multiple oncoproteins or tumor suppressor proteins.
- Mutations affecting epigenetic regulators such as histone-modifying enzymes or chromatin remodelers are associated with a variety of tumors.

25.3 Dysregulation of Cell Growth and Developmental Pathways Initiates Tumorigenesis

Uncontrolled cellular proliferation is the central hallmark of cancer. We have already seen that many of the known oncogenic drivers of cancer are in genes involved in the pathways that keep growth of normal tissues in check by a balance of growth-promoting and growth-inhibiting signals. In this section, we examine these pathways in greater detail, with an emphasis on the mechanism by which oncogenic mutations exert their effects.

Receptor Mutations Can Cause Proliferation in the Absence of External Growth Factors

Oncogenes encoding cell-surface receptors that transduce growth-promoting signals have been associated with several types of cancer. A major class of these receptors, known as *receptor tyrosine kinases (RTKs)*, have intrinsic protein tyrosine kinase activity in their cytosolic domains, which is quiescent until activated. As detailed in Chapter 16, ligand binding to the external domains of RTKs leads to their dimerization and activation of their kinase activity, initiating

an intracellular signaling pathway that ultimately promotes proliferation.

In some cases, a point mutation changes a wild-type RTK into one that dimerizes and is constitutively active even in the absence of ligand. For instance, a single point mutation converts the normal human EGF receptor 2 (HER2) into the NEU oncoprotein ("NEU" for its first known role, in neuroblastoma) (Figure 25-13, *left*). Similarly, human tumors called *multiple endocrine neoplasia type 2* produce a constitutively active dimeric glia-derived neurotrophic factor (GDNF) receptor that results from a point mutation in the extracellular domain. The GDNF receptor and the HER2 receptor are both protein tyrosine kinases, so by the signal transduction pathways detailed in Chapter 16, the constitutively active forms excessively activate their downstream target proteins, which ultimately promote cell cycle progression, cell survival and proliferation. In other cases, deletion of much of the extracellular ligand-binding domain produces a constitutively active oncogenic receptor. For example, deletion of the extracellular domain of the normal EGF receptor (Figure 25-13, *right*) converts it to the dimeric ErbB oncoprotein (from *er*ythro*b*lastosis virus, in which a viral version of the altered gene was first identified). Mutations leading to overproduction of a normal RTK can also be oncogenic. For instance, many human breast cancers overproduce a normal HER2 receptor because of amplification of its encoding gene. As a result, the cells are stimulated to proliferate in the presence of very low

concentrations of EGF and related hormones, concentrations too low to stimulate proliferation of normal cells (see Chapter 16).

FIGURE 25-13 Effects of oncogenic mutations in proto-oncogenes that encode cell-surface receptors. *Left:* A mutation that alters a single amino acid (valine to glutamine) in the transmembrane region of the HER2 receptor causes dimerization of the receptor, even in the absence of the normal EGF-related ligand, transforming it into the oncoprotein NEU, a constitutively active protein tyrosine kinase. *Right:* A deletion that causes loss of the extracellular ligand-binding domain in the EGF receptor leads, for unknown reasons, to constitutive activation of the kinase activity of the resulting oncoprotein, ErbB.

Many Oncogenic Mutations Constitutively Activate Signal-Transducing Proteins

A large number of oncogenes are derived from proto-oncogenes whose encoded proteins are components or regulators of signal transduction pathways — most prominent among them the Ras pathway. As we saw in Chapter 16, Ras is a key component in the transduction of signals from activated receptors to a cascade of protein kinases. In the first part of this pathway, a signal from an activated RTK is carried via two adapter proteins to Ras, converting it to the active GTP-bound form (see Figure 16-10). In the second part of the pathway, activated Ras transmits the signal via two intermediate protein kinases to MAP kinase. The activated MAP kinase then phosphorylates a number of transcription factors that induce synthesis of important growth and proliferation proteins (see Figures 16-13 and 16-14). Virtually every component of this

RTK/Ras/MAP kinase signaling cascade has been identified as an oncogene or tumor suppressor gene (Figure 25-14).

FIGURE 25-14 RTK/Ras/MAP kinase pathway components are frequently mutated in cancer. Oncogenic mutations that activate the RTK/Ras/MAP kinase pathway have been identified in many human cancers. Most components,

highlighted in green, activate the pathway and oncogenic mutations cause a gain of function. In contrast, NF1, highlighted in red, normally inactivates the pathway and the oncogenic mutations cause a loss of function of both copies of the gene.

Among the best studied oncogenes are the RAS^D genes themselves, which were the first nonviral oncogenes to be recognized. Any one of a number of changes in Ras can lead to its uncontrolled and therefore dominant activity. In particular, if a point mutation substitutes any other amino acid for the glycine at position 12 in the Ras sequence, the normal protein is converted into a constitutively active oncoprotein (see Chapter 16). This single mutation reduces the protein's GTPase activity, thus maintaining Ras in the active GTP-bound state. Activating Ras mutations short-circuit the first part of the RTK pathway, making upstream activation triggered by ligand binding to the receptor unnecessary. Constitutively active Ras oncoproteins are produced by many types of human tumors, including bladder, colon, mammary, skin, and lung carcinomas, neuroblastomas, and leukemias.

Constitutive Ras activation can also arise from loss-of-function mutations in a GTPase-activating protein (GAP). The normal function of a GAP is to accelerate hydrolysis of GTP and thus the conversion of active GTP-bound Ras to inactive GDP-bound Ras (see Figure 3-35). Loss-of-function mutations in the Ras-GAP protein, the product of the *NF1* gene, leads to sustained activation of downstream signal-transducing proteins. The relationship between

RAS, an oncogene, and *NF1*, a tumor suppressor gene acting in the same pathway, is a good example of the regulatory circuit shown in Figure 25-12. *NF1* was first discovered as the underlying cause of the familial cancer syndrome neurofibromatosis. Individuals who have inherited a single mutant *NF1* allele then develop neurofibromas, a benign tumor of the sheath cells that surround nerves, caused by loss of both alleles through LOH.

Oncogenes encoding other altered components of the RTK/Ras/MAP kinase pathway have also been identified (see Figure 25-14). For example, constitutively active forms of Raf have been identified in approximately 50 percent of melanomas. As in the case of constitutively active forms of Ras, these mutant Raf forms no longer require regulatory signals coming from the cell surface and signal continuously for cell growth and proliferation.

Growth Control Pathways Ultimately Regulate Initiation of the Cell Cycle

Growth stimulatory pathways such as the RTK/Ras/MAP kinase pathway ultimately have two outputs: transcription of a set of genes required for cell growth and activation of the cell cycle to initiate a new round of cell division. During the cell cycle, once a cell progresses past a certain point in G_1, called the **restriction point**, it becomes irreversibly committed to entering S phase and replicating

its DNA. Cyclin Ds, cyclin-dependent kinases (CDKs), and the Rb protein are all elements of the control system that regulates passage through the restriction point. Many of these proteins that regulate cell cycle initiation are targets for oncogenic mutations.

The pathway that controls entry into the cell cycle is estimated to be misregulated in approximately 80 percent of human cancers. At the heart of this pathway are cyclin D–CDK4/6 complexes and the transcriptional repressor Rb (see Figure 19-16). The expression of cyclin D genes is induced by many extracellular growth factors, or *mitogens*. These cyclins assemble with a partner, CDK4 or CDK6, to generate catalytically active cyclin-CDK complexes whose kinase activity promotes progression through G_1. Mitogen withdrawal prior to passage through the restriction point leads to accumulation of two CDK inhibitors. As described in Chapter 19, these two proteins, p15 and p16, bind to cyclin D–CDK4/6 complexes and inhibit their activity, thereby causing G_1 arrest.

Most tumors contain an oncogenic mutation that causes the overproduction or loss of one of the components of the pathway that controls entry into S phase, so that the cells are propelled into S phase in the absence of the proper extracellular growth signals. For example, elevated levels of cyclin D1, one of the three cyclin Ds, are found in many human cancers. One mechanism that results in overproduction of cyclin D is translocation. In certain tumors of antibody-producing B lymphocytes, the *cyclin D1* gene is

translocated such that its transcription is under the control of an antibody-gene enhancer, causing elevated cyclin D1 production throughout the cell cycle irrespective of extracellular signals. That cyclin D1 can function as an oncoprotein was shown by studies with transgenic mice in which the *cyclin D1* gene was placed under the control of an enhancer specific for mammary duct cells. Initially, the duct cells underwent hyperproliferation, and eventually breast tumors developed in these transgenic mice. A second mechanism that can lead to overproduction of cyclin D is gene amplification. Amplification of the *cyclin D1* gene and concomitant overproduction of the cyclin D1 protein is common in human breast cancers; the extra cyclin D1 helps to drive cells through the cell cycle.

We have already seen that inactivating mutations in both *RB* alleles lead to childhood retinoblastoma, a relatively rare type of cancer. However, loss-of-function mutations in the *RB* gene are also found in the more common cancers that arise later in life (see Figure 25-11). These tissues, unlike retinal tissue, probably produce other proteins (e.g., p107 and p130, both structurally related to *RB*) whose function is redundant with that of *RB*, and thus *RB* is not so critical for preventing cancer in these tissues. In the retina, however, regulation of cell cycle entry appears to rely exclusively on the Rb protein, which is why patients heterozygous for the *RB* gene first develop tumors in this tissue. Rb function can be eliminated not only by inactivating mutations, but also by the binding of an inhibitory protein, designated *E7*, that is encoded by human

papillomavirus (HPV), another nasty viral trick to create virus-producing tissue. At present, this binding is known to occur only in cervical and oropharyngeal cancers.

The proteins that function as cyclin-CDK inhibitors are also targets for oncogenic mutations. In particular, loss-of-function mutations in p16 (*CDKN2A*) that prevent it from inhibiting cyclin D–CDK4/6 kinase activity are among the most common oncogenic drivers in several cancers (see Figure 25-11 and Table 25-2). Loss of p16 mimics overproduction of cyclin Ds and thus p16 normally acts as a tumor suppressor. Although the *p16* tumor suppressor gene is deleted in some human cancers, the *p16* sequence is normal in others. In some of these latter cancers (e.g., lung cancer), the *p16* gene, or genes encoding other functionally related proteins, is inactivated by hypermethylation of its promoter region, which prevents its transcription. What promotes this change in the methylation of *p16* is not known, but it prevents production of this important cell cycle control protein.

The locus encoding p16 is highly unusual in that it encodes no less than three tumor suppressor genes, which makes it the most vulnerable locus in the human genome to oncogenic changes. In addition to harboring the p16-encoding gene, *CDKN2A*, it has the *CDKN2B* locus immediately upstream, which encodes p15, another cyclin D–CDK4/6 inhibitor (Figure 25-15). The locus also encodes a key activator of the tumor suppressor p53. This protein, p14ARF

(p19ARF in the mouse), is encoded by an exon upstream of the first *CDKN2A* exon and shares its exon 2 and exon 3 with *CDKN2A*. As we will see in Section 25.4, this protein controls the stability of p53. Thus mutations in this locus can simultaneously affect the two major tumor-suppressor pathways in the cell, the Rb and p53 pathways.

FIGURE 25-15 The p15-ARF-p16 locus encodes three tumor suppressor genes. Exons are designated as *E*. The two *p15* exons (orange) are located upstream of the *ARF* locus. *ARF* (blue) is encoded by a unique E1β exon but shares exons E2 and E3 with *p16* (green). *ARF* encodes a p53 activator.

Inappropriate Production of Nuclear Transcription Factors Can Induce Transformation

Mutations that create oncogenes or inactivate tumor suppressor genes eventually cause broad changes in gene expression. These changes can be measured by comparing the amounts of different

mRNAs produced in normal cells and in tumor cells. Since the most direct effect on gene expression is exerted by transcription factors, it is not surprising that many oncogenes encode transcription factors. Two such transcription factors with a clear role in tumorigenesis are the FOS and MYC proteins, which stimulate transcription of genes encoding proteins that promote progression through the G_1 phase of the cell cycle and the G_1-to-S transition. We discuss the deregulation of these proteins below.

JUN and FOS were initially identified in transforming retroviruses and later found to be overexpressed in some human tumors. The *JUN* and *FOS* proto-oncogenes encode proteins that sometimes associate to form a heterodimeric transcription factor, called *AP1,* that binds to a sequence found in promoters and enhancers of many genes (see Figure 8-26a and Chapter 16). These proteins function as oncoproteins by activating the transcription of key genes that encode growth-promoting proteins and by inhibiting the transcription of growth-repressing genes.

Many nuclear proto-oncogene proteins are produced when normal cells are stimulated to grow, indicating their direct role in growth control. For example, platelet-derived growth factor (PDGF) treatment of quiescent mouse 3T3 cells induces an approximately 50-fold increase in the production of the transcription factors FOS as well as MYC, the products of the *FOS* and *MYC* proto-oncogenes. Initially, there is a transient rise of FOS and later a more prolonged

rise of MYC (Figure 25-16). The levels of both proteins decline within a few hours, a regulatory effect that may, in normal cells, help to avoid cancer.

EXPERIMENTAL FIGURE 25-16 Addition of serum to quiescent 3T3 cells yields a marked increase in the activity of two proto-oncogene products, FOS and MYC. Serum contains factors such as platelet-derived growth factor (PDGF) that stimulate the growth of quiescent cells. One of the earliest effects of growth factors is to induce expression of *FOS* and *MYC*, whose encoded proteins are transcription factors.

[Data from M. E. Greenberg and E. B. Ziff, 1984, *Nature* **311**:433.]

The oncogenic forms of *FOS* and *MYC* are due to gain-of-function mutations. In normal cells, the mRNAs for these genes and the proteins they encode are intrinsically unstable and degrade rapidly after the genes are transcribed. Some of the genetic changes that

turn *FOS* from a normal gene into an oncogene involve deletions of the sequences that normally make the *FOS* mRNA and protein short-lived. Conversion of the *MYC* proto-oncogene into an oncogene can occur by different mechanisms. In cells of the human tumor known as **Burkitt's lymphoma**, the *MYC* gene is translocated to a site near the heavy-chain antibody genes, which are normally active in antibody-producing white blood cells (Figure 25-17). The *MYC* translocation is a rare aberration of the normal DNA rearrangements that occur during maturation of antibody-producing cells. The translocated *MYC* gene, now regulated by the antibody-gene enhancer, is continually highly expressed, causing the cell to become cancerous. Localized amplification of a segment of DNA containing the *MYC* gene, which occurs in several human tumors, also causes inappropriately high production of the otherwise normal MYC protein. This mechanism of oncogenic activation is similar to the formation of BCR-ABL oncogene by a translocation that produces the Philadelphia chromosome.

FIGURE 25-17 Chromosomal translocation in Burkitt's lymphoma. As a result of a translocation between chromosomes 8 and 14, the *MYC* gene is placed adjacent to the gene for part of the antibody heavy chain (C_H), leading to overproduction of the MYC transcription factor in lymphocytes and hence their growth into a lymphoma.

The *MYC* gene encodes a basic helix-loop-helix protein that acts as part of a set of interacting proteins that can dimerize in various combinations, bind to DNA, and coordinately regulate the transcription of target genes. Other members of this protein set include MAD, MAX, and MNT. MAX can heterodimerize with MYC, MAD, and MNT. MYC-MAX dimers regulate genes that control proliferation, such as cyclins. MAD proteins inhibit MYC proteins, which has led to an interest in using MAD proteins, or drugs that stimulate MAD proteins, to rein in excessive MYC activity that contributes to tumor formation. MYC protein complexes affect transcription by recruiting chromatin-modifying complexes containing histone acetyl transferases (which usually stimulate transcription; see Chapter 8) to MYC target genes. MAD and MNT work with the SIN3 co-repressor protein to bring in histone deacetylases that help to block transcription. Together, all these proteins form a regulatory network that employs protein-protein association, variations in DNA binding, and transcriptional regulation to control cell proliferation. Overproduction of MYC protein tips the scales in favor of cell growth and division.

Aberrations in Signaling Pathways That Control Development Are Associated with Many Cancers

During normal development, secreted signals such as Hedgehog (Hh), Wnt, and TGF-β are used to direct cells to particular developmental fates, which may include the property of rapid cell cycling. The effects of such signals must be regulated so that growth is limited to the right time and place. Among the mechanisms available for reining in the effects of these powerful developmental signals are inducible intracellular antagonists, receptor blockers, and competing signals. Mutations that prevent such restraining mechanisms from operating are likely to be oncogenic, causing inappropriate or cancerous growth.

The Hedgehog signaling pathway, which is used repeatedly during development to control differentiation, is a good example of a signaling pathway implicated in cancer induction. In the skin and cerebellum, one of the human Hh proteins, Sonic Hedgehog, stimulates cell division by binding to and inactivating a membrane protein called *Patched1 (PTC1)* (see Figure 16-29). Loss-of-function mutations in *PTC1* permit cell proliferation in the absence of an Hh signal; thus *PTC1* is a tumor suppressor gene. People who inherit a defective copy of *PTC1* have a propensity to develop skin and brain cancer; either can occur when the remaining *PTC1* allele is lost through the mechanism of LOH that we saw for RB and NF1 cancer

syndromes. Spontaneous mutations in both copies of this gene have also been observed in sporadic cases of these cancers. Mutations in other genes in the Hh signaling pathway are also associated with cancer. Some such mutations create oncogenes that turn on Hh target genes inappropriately; others are recessive mutations that affect negative regulators such as PTC1.

Many of the signaling pathways described in Chapters 16 and 20 also play roles in controlling embryonic development and cell proliferation in adult tissues. In recent years, mutations affecting components of most of these signaling pathways have been linked to cancer. Indeed, once one gene in a developmental pathway has been linked to a type of human cancer, knowledge of that pathway gleaned from model organisms such as worms, flies, or mice allows focused investigations of the possible involvement of additional pathway genes in other cases of the cancer. For example, *APC*, a gene that is mutated early on in colon cancer, is now known to be part of the Wnt signaling pathway (see Chapter 16). That knowledge, in turn, led to the discovery of β-catenin mutations in colon cancer.

Mutations in tumor-suppressor developmental genes promote tumor formation in tissues where the affected gene normally acts to restrain growth. For example, transforming growth factor β (TGF-β), despite its name, primarily acts to inhibit proliferation of many cell types, including most epithelial and immune-system cells. Binding of TGF-β to its receptor activates cytosolic Smad transcription

factors (see Figure 16-24). After translocating to the nucleus, Smads can promote expression of the gene encoding p15, an inhibitor of cyclin-dependent kinase 4 (CDK4), which causes cells to arrest in G_1. TGF-β signaling also promotes expression of genes encoding extracellular matrix proteins and plasminogen activator inhibitor 1 (PAI-1), which reduces the plasmin-catalyzed degradation of the matrix. Loss-of-function mutations in either TGF-β receptors, as noted above, or in Smads thus promote cell proliferation and probably contribute to the invasiveness and metastasis of tumor cells (Figure 25-18). Such mutations have in fact been found in a variety of human cancers. For example, deletion of the *Smad4* gene occurs in many human pancreatic cancers; retinoblastoma and colon cancer cells lack functional TGF-β receptors and therefore are unresponsive to TGF-β growth inhibition. Originally Smad4 was called *DPC (deleted in pancreatic carcinoma)*.

FIGURE 25-18 Effect of loss of TGF-β signaling. Binding of TGF-β, an anti-growth factor, to its receptor causes activation of Smad transcription factors. In the absence of effective TGF-β signaling owing to either a receptor mutation or a Smad mutation, cell proliferation and invasion of the surrounding extracellular matrix increase. See X. Hua et al., 1998, *Genes Dev.* **12**:3084.

Experimental Reconstruction of the Multi-Hit Model for Cancer

As we have seen from the sequencing of cancer genomes, a typical tumor may have acquired thousands of mutations, five of which have been selected for because they are drivers of oncogenesis; many of which are genes we just discussed that regulate cell growth and division. As the data in Figure 25-19 show, the incidence of many types of human cancer increases drastically with age, indicating that it can take decades for the required multiple mutations to occur. This model for the slow progression of cancer raises fundamental questions about the sequence of events needed to lead to a tumor. In what sequential order do the driver mutations occur? Do different driver mutations act synergistically? Answers to these questions are necessary to complete the picture of how cancer forms and will be important for strategies for early diagnosis and cancer prevention.

FIGURE 25-19 The incidence of human cancers increases as a function of age. The marked increase in the incidence of cancer with age is consistent with the multi-hit model of cancer induction. Note that the logarithm of annual incidence is plotted versus the logarithm of age.

[Data from B. Vogelstein and K. W. Kinzler, 1993, *Trends Genet*. **9**:138–141.]

Experimental reconstruction of a multi-hit progression has been carried out with transgenic mice, which have shown that a variety of combinations of oncogenes can cooperate in causing cancer. For example, mice have been made that carry either the mutant RAS^{V12} dominant oncogene or the *MYC* proto-oncogene, in each case under the control of a mammary-cell-specific promoter/enhancer. This promoter is induced by endogenous hormone levels and tissue-

specific regulators, leading to overexpression of *MYC* or RAS^{V12} in breast tissue.

As noted, the MYC protein is a transcription factor that induces expression of many genes required for the transition from the G_1 to the S phase of the cell cycle. Heightened transcription of *MYC* in these mice mimics previously identified oncogenic mutations that increase *MYC* transcription, converting the proto-oncogene into an oncogene. By itself, the *MYC* transgene causes tumors only after 100 days, and then in only a few mice; clearly only a minute fraction of the mammary cells that overproduce the MYC protein actually become malignant. Production of the mutant Ras^{V12} protein alone causes tumors earlier, but still slowly and with about 50 percent efficiency over 150 days. When the *MYC* and Ras^{V12} overexpressing transgenic mice are crossed, however, all mammary cells in their offspring overproduce both MYC and Ras^{V12}. In these mice, tumors arise much more rapidly, and all animals succumb to cancer (Figure 25-20). Such experiments emphasize the synergistic effects of multiple oncogenes. They also suggest that the long latency of tumor formation, seen even in the double-transgenic mice, is due to the need to acquire still more mutations.

EXPERIMENTAL FIGURE 25-20 The kinetics of tumor appearance in female mice carrying either one or two oncogenic transgenes shows the cooperative nature of multiple mutations in cancer induction. Each of the transgenes was driven by the mouse mammary tumor virus (MMTV) breast-specific promoter. The hormonal stimulation associated with pregnancy activates the MMTV promoter and hence the overexpression of the transgenes in mammary tissue. The graph shows the time course of tumorigenesis in mice carrying either *MYC* or Ras^{V12} transgenes as well as in the progeny of a cross of *MYC* carriers with Ras^{V12} carriers, which contain both transgenes. The results clearly demonstrate the cooperative effects of multiple mutations in cancer induction. See E. Sinn et al., 1987, *Cell* **49**:465.

The Succession of Oncogenic Mutations Can Be Traced in Colon

Cancers

A direct way to reconstruct the progression of a tumor is to take sequential samples from a slowly developing tumor. Surgeons can obtain fairly pure samples of many human cancers, but since the tumor is observed at only one time, its exact stage of progression cannot be easily determined. An exception is colon cancer, which evolves through distinct, well-characterized morphological stages. Its intermediate stages — polyps, benign adenomas, and carcinomas — can be isolated by a surgeon during colonoscopies, allowing mutations that occur in each of these stages to be identified. Numerous studies have shown that colon cancer arises from a series of mutations that commonly occur in a well-defined order, providing strong support for the **multi-hit model** (Figure 25-21).

FIGURE 25-21 The development and metastasis of human colorectal cancer and its genetic basis. A mutation in the *APC* tumor suppressor gene in a single epithelial cell causes the cell to divide (although surrounding epithelial cells do not), forming a mass of localized benign tumor cells, called a *polyp*. Subsequent mutations lead to expression of a constitutively active Ras protein and loss of the tumor suppressor gene *p53.* These mutations, together with additional genetic changes yet to be identified, generate a malignant cell. The cell continues to divide, and its progeny invade the basement membrane that surrounds the tissue, but do not penetrate the basement membrane of capillaries (*bottom left*). Some tumor cells spread into blood vessels that will distribute them to other sites in the body (*bottom right*). Additional mutations permit the tumor cells to exit from the blood vessels and proliferate at distant sites. See B. Vogelstein and K. W. Kinzler, 1993, *Trends Genet*. **9**:138–141.

Insight into the progression of colon cancer first came from the study of inherited predispositions to colon cancer such as familial adenomatous polyposis (FAP). Mutations in the Wnt signaling pathway have been identified in many of these syndromes, and it is now believed that deregulation of Wnt signaling results in formation of polyps (precancerous growths) on the inside of the colon wall — not only in people with inherited polyposis syndromes, but also in people afflicted with sporadic (noninherited) forms of colon cancer. The APC (*a*denomatous *p*olyposis *c*oli) protein is a negative regulator of Wnt signaling (see Figure 16-26), which promotes cell cycle entry by activating expression of the *MYC* gene. The absence of functional APC protein thus leads to inappropriate production of MYC, and cells homozygous for *APC* mutations proliferate at a rate higher than normal and form polyps. Loss-of-function mutations in the *APC* gene are the most frequent mutations found in early stages of colon cancer. Most of the cells in a polyp contain the same one or two mutations in the *APC* gene that result in its loss or inactivation, indicating that they are clones of the cell in which the original mutation occurred. Thus *APC* is a tumor suppressor gene, and both alleles of the *APC* gene must carry an inactivating mutation for polyps to form because cells with one wild-type *APC* allele express enough APC protein to function normally.

If one of the cells in a polyp undergoes another mutation, this time an activating mutation of the *ras* gene, its progeny divide in an even more uncontrolled fashion, forming a larger adenoma. Inactivation

of the *p53* gene follows and results in the gradual loss of normal regulation and the consequent formation of a malignant carcinoma (see Figure 25-21). The p53 protein is a tumor suppressor that halts progression through the cell cycle in response to DNA damage and other stresses and can induce apoptosis (see Section 25.4). While the three "hits" listed here are certainly crucial parts of the picture, there are likely to be additional contributing genetic events. Not every colon cancer, however, acquires all the later mutations or acquires them in the order depicted in Figure 25-21. Thus different combinations of mutations may result in the same phenotype.

DNA from different human colon carcinomas generally contains mutations in all three genes mentioned here — loss-of-function mutations in the tumor suppressors *APC* and *p53* and an activating (gain-of-function) mutation in the oncogene *K-RAS* (one of the *RAS* family of genes) — establishing that multiple mutations in the same cell are needed for the cancer to form. Some of these mutations appear to confer growth advantages at an early stage of tumor development, whereas other mutations promote the later stages, including invasion and metastasis, which are required for the malignant phenotype.

For the majority of tumors that are only biopsied or removed at a late stage in cancer development there are now sequencing-based methods that allow some of the events in cancer progression to be reconstructed. The idea is to gain information from multiple

individual cells from the tumor to create a lineage map for the tumor as a whole. To see how this analysis works, imagine a simple case for a tumor that arose as the result of two oncogenic driver mutations. At the time that the tumor is biopsied, all of the cells should have the first driver mutation that occurred, whereas only some of the tumor cells would have the second. This method will allow the order of appearance to be determined for any two oncogenic driver mutations as long as at least a few cells in the tumor can be found that lack one of the mutations. This method for reconstructing cell lineages within a tumor is now feasible because of advances in next generation sequencing that enable genomic sequence information to be obtained from a single tumor cell.

Cancer Development Can Be Studied in Animal Models

Genetically engineered mice have also provided tremendous insights into the steps of tumor initiation and progression. Using mouse models to study cancer is not always straightforward, however. Many tumor suppressor genes serve essential functions during normal mouse development, so mice lacking both copies of these genes are not viable. The essential functions of these genes during early embryogenesis preclude the study of their role in tumor progression. To circumvent this problem, researchers have begun to employ conditional *knock-in* and *knockout* strategies that

allow for the targeted activation or inactivation of a gene in a certain tissue or at a certain stage of development.

In the conditional mouse model, an allele of a particular oncogene or tumor suppressor gene is wild type until activated or inactivated with exogenous chemicals or viruses in a tissue- or time-specific manner. At the heart of these conditional systems are the Cre and FLP recombinases. These recombinases facilitate homologous recombination between *loxP* and *FRT* sites, respectively (Figure 25-22; see also Figure 6-40). When the recombinases are under the control of a tissue-specific promoter, recombination occurs only in the tissue that produces the recombinase. The recombinase method can be used in two ways. First, the recombinase target sites may flank an exon. Upon induction of the recombinase, that exon is lost and the gene is inactivated (Figure 25-22a). This method is especially useful for inactivating tumor suppressor genes in a tissue-specific manner. Second, expression of an oncogene can be controlled by introducing into the oncogene an additional exon that contains a stop codon, which makes the gene nonfunctional. However, if the additional exon is flanked by recombinase target sites, the oncogene will be expressed upon induction of the recombinase (Figure 25-22b). Using this system, researchers have examined the role of oncogenic forms of Ras in the mouse and have, using a conditional oncogenic *ras* allele, created a mouse model of human lung cancer.

FIGURE 25-22 Conditional mouse models of cancer. In the inactivating system (a), an exon of interest is flanked by two *loxP* or *FRT* sites as shown. Expression of the Cre or FLP recombinase leads to homologous recombination between the two *loxP* and *FRT* sites, respectively. This recombination leads to excision of the exon, rendering the gene nonfunctional. In the activating system (b), an additional exon with a stop codon is introduced into the gene of interest, making the gene nonfunctional. This exon is flanked by *loxP* or *FRT* sites. When Cre or FLP recombinase is induced, the stop codon–containing exon is recombined out, and the gene of interest is expressed.

Molecular Cell Biology Is Changing How Cancer Is Diagnosed and Treated

The identification of oncogenic driver mutations, such as mutations in genes that regulate cell growth and development pathways, has not only provided us with a molecular understanding of how cancer arises and progresses, but has also revolutionized the way cancers are diagnosed and treated. Historically, tumors were characterized and treated based on the organ in which they arose and the

histologic characteristics of the tumor cells when they were viewed under the microscope. We now know that similarly appearing tumors may behave very differently and can be better separated into specific tumor subsets by examining their genomic changes. This type of characterization, which is extensively used in breast and brain cancer diagnosis, has significant implications for treatment. Each difference between the cancer cells and normal cells provides a new opportunity to identify a specific drug or treatment that kills only the cancer cells or at least stops their uncontrolled growth. Thus knowledge of the molecular cell biology of a tumor is critical information that can be exploited by researchers to develop anticancer treatments that more precisely target cancer cells.

Breast cancer provides a good example of how molecular cell biology techniques have affected treatments, both curative and palliative. Breast cancer is the second most frequent cause of women's cancer deaths. Breast cancers are often diagnosed during routine mammogram (x-ray) examinations. Typically, a very small biopsy is taken with a needle to confirm the diagnosis and is tested with antibodies to determine whether a high level of estrogen or progesterone receptors is present. These steroid receptors are capable of stimulating tumor growth and are sometimes expressed at high levels in breast cancer cells. If either receptor is present, it is exploited in the treatment. A drug called *tamoxifen*, which inhibits the estrogen receptor (see Figure 8-26), can be used to deprive the tumor cells of this growth-stimulating hormone. The biopsy is also

tested for amplification of the proto-oncogene *HER2/NEU*, which, as we saw in Chapter 16, encodes the human EGF receptor HER2. A monoclonal antibody specific for HER2 has been a strikingly successful new treatment for the subset of breast cancers that overproduce HER2. HER2 antibody injected into the blood recognizes HER2 and causes it to be internalized, selectively killing the cancer cells without any apparent effect on normal breast (and other) cells that produce only moderate amounts of HER2. More recently, covalent conjugates of HER2 monoclonal antibodies with a potent cytotoxic drug became available to target these agents into HER2-overproducing tumor cells, enhancing the killing effects of these monoclonal antibodies. These advanced antibody conjugates are used as a second line of defense for tumors that have resisted more conventional treatments.

Breast cancer is still initially treated with a combination of surgery, radiation therapy, and chemotherapy. The first step is surgical resection (removal) of the tumor and examination of lymph nodes for evidence of metastatic disease. The subsequent treatment typically involves 8 weeks of chemotherapy with several different types of agents and 6 weeks of radiation. These harsh treatments are designed to kill the dividing cancer cells; however, they also cause a variety of side effects, including suppression of blood cell production, hair loss, nausea, and neuropathy. These effects can reduce the strength of the immune system, risking infection, and cause weakness due to poor oxygen supply. To help offset these

effects, patients are given the cytokine G-CSF to promote the formation of neutrophils (a type of white blood cell that fights bacterial and fungal infections) and erythropoietin (Epo) to stimulate red blood cell formation (see Chapter 16). Even with this aggressive treatment, about a third of women will nevertheless succumb to cancer over the next 10 years. This risk can be reduced by 15 percent by hormone-blocking treatment such as tamoxifen and by another 10 percent by treatment with antibodies against the HER2/NEU oncoprotein. In aggregate, advanced molecular methods can reduce morbidity from breast cancer by as much as 25 percent.

KEY CONCEPTS OF SECTION 25.3

Dysregulation of Cell Growth and Developmental Pathways Initiates Tumorigenesis

- Mutations that permit receptors for growth factors to dimerize in the absence of their normal ligands lead to constitutive receptor activity. Overproduction of growth-factor receptors can have the same effect and lead to abnormal cell proliferation.
- Most tumor cells produce constitutively active forms of one or more intracellular signal-transducing proteins, causing growth-promoting signaling in the absence of normal growth factors.
- A feature of the proliferation of most cancers is unregulated passage through the restriction point of the cell cycle. This can be caused by gain-of-function mutations in cyclin D1 or loss-of-function mutations in p16 or RB.
- Inappropriate production of nuclear transcription factors such as FOS, JUN, and MYC can induce transformation. In Burkitt's lymphoma cells, *MYC* is translocated close to an antibody gene, leading to overproduction of MYC.
- Loss of signaling by TGF-β, a negative growth regulator, promotes cell proliferation and development of malignancy.

- A typical tumor carries about five oncogenic mutations in genes of cell growth and development pathways that are acquired over many years. A major unsolved problem in understanding how cancer progresses will depend on reconstruction of the sequential order of these mutational events.
- Colon cancer develops through distinct, identifiable morphological stages that can be traced to specific oncogenic mutations.
- Genome sequencing of multiple individual cells in a tumor can enable the lineages of cells with specific oncogenic mutations to be reconstructed.

25.4 Evasion of Programmed Cell Death and Immune Surveillance Processes

So far in this chapter, we have seen that early stages of the progression of cancer involve two types of oncogenic mutations: those discussed in Section 25.2 that compromise DNA repair and lead to destabilization of the genome, and those discussed in Section 25.3 that activate growth-promoting pathways and inactivate growth-inhibiting pathways. In addition to these mutations that drive oncogenesis, many cells that have reached this precancerous stage also carry a significant burden of adventitious mutations, chromosomal rearrangements, and other defects in chromosomal DNA. Cells that carry significant chromosomal abnormalities or irreparable damage to their DNA will enter the apoptotic pathway and be targeted for programmed cell death. Cells that carry many point mutations in protein-coding genes will express mutant proteins that may cause them to be recognized and targeted for destruction by cells of the immune system. Although we have little direct visibility into what happens to small numbers of precancerous cells when they do arise, it is likely that the vast majority of them are efficiently eliminated by one or both of these mechanisms. For this reason, the tumor cells that we eventually do observe owe their existence to having acquired mutations that allowed them to evade both apoptosis and immune surveillance.

The acquisition by most cancer cells of mutations that block the apoptotic pathway and of other mutations that suppress an immune response to them is a powerful example of how cancer progression results from an evolutionary process of mutation and selection. We will see in this section some of the kinds of oncogenic mutations that allow tumor cells that carry a high mutational load to survive. At the end of the section, we will highlight some of the promising new therapies that are based on reactivating the immune system to target cancer cells.

Oncogenic Driver Mutations Enable Cancer Cells to Evade Apoptosis

As we saw in Chapter 22, programmed cell death, or apoptosis, plays an important role in development. For example, during mammalian limb formation apoptosis is responsible for sculpting the digits out of a paddle-shaped limb bud. In addition, apoptosis serves an editing function to maintain the organization of mature tissues by removing abnormal excesses of cells not needed for development of a working organ and by removing cells that have been compromised by errors in mitosis or DNA damage (see Chapter 22). For some cells, apoptosis appears to be the outcome by default, and signals from the PI 3-kinase/AKT pathway are required to ensure cell survival (see Figure 22-42).

A major class of oncogenic mutations blocks apoptosis, allowing tumor cells to continue to proliferate inappropriately. For example, chronic lymphocytic leukemia (CLL) occurs because cells survive when they should not. The cells accumulate slowly, and most are not actively dividing, but they do not die. CLL cells have chromosomal translocations that activate the *BCL2* gene, a critical blocker of apoptosis (see Figure 22-42). The resultant inappropriate overproduction of the BCL2 protein prevents normal apoptosis and allows survival of these tumor cells. CLL tumors are therefore attributable to a failure of cell death. Another dozen or so proto-oncogenes that are normally involved in negatively regulating apoptosis have been found to be mutated to become oncogenes. Overproduction of their encoded proteins prevents apoptosis even when death is needed to stop cancer cells from growing.

p53 Can Activate Either the DNA Damage Checkpoint or Apoptosis in Response to DNA Damage

We have already seen that the p53 protein is a central player in tumorigenesis, and it is thought that most, if not all, human tumors have mutations either in p53 itself or in proteins that regulate p53 activity. In Section 25.2, we saw that p53 has a major part in causing an arrest in the cell cycle in response to DNA damage. Because cells carrying oncogenic p53 mutations do not arrest to give enough time

for the DNA damage to be repaired, these mutants have unstable genomes and accumulate somatic mutations. p53 mutant cells also do not respond to extensive DNA damage by entering the apoptotic pathway and thus can continue to proliferate even after they have sustained damage that would cause a normal cell to be removed by programmed cell death.

Although the oncogenic form of p53 is due to a loss of function, it is nevertheless possible for certain missense mutations in only one of the two *p53* alleles in a cell to abrogate almost all p53 DNA activity. This behavior comes from the fact that the active form of p53 is tetramer of four identical subunits and mixed complexes that contain at least one defective subunit have reduced ability to activate transcription. Precancerous cells with one missense mutant of p53 are probably selected for because of a proliferative growth advantage. However, the loss of function is incomplete and in order to proliferate more rapidly tumor cells often lose the remaining functional allele. This unusual feature of positive selection for a first and then a second mutation in the p53 gene may explain why tumor cells so frequently carry oncogenic driver mutations in p53.

We do not yet understand why p53 causes cell cycle arrest under some circumstances and apoptosis under others, but both responses can occur as a result of p53 being stabilized in response to DNA damage. Unlike other cell cycle proteins, p53 is present at very low levels in normal cells because it is extremely unstable and rapidly

degraded. The activity of p53 is normally kept low by a protein called *MDM2*. When MDM2 is bound to p53, it inhibits the transcription-activating ability of p53 and at the same time, because it has E3 ubiquitin ligase activity, catalyzes the ubiquitinylation of p53, thus targeting it for proteasomal degradation. After DNA damage, ATM or ATR are recruited to the sites of damage and their serine kinase activity is activated. Phosphorylation of p53 on a serine residue in the N-terminus of the protein by ATM or DNA-PK displaces bound MDM2 from p53, thereby stabilizing it (Figure 25-23). The stabilized p53 activates transcription of the gene encoding p21, which binds to and inhibits mammalian CDK2, CDK1, and CDK4/6 complexes (see Figure 19-34).

FIGURE 25-23 Arrest in G_1 in response to DNA damage. The kinase activity of ATM, ATR, and DNA-PK is activated in response to DNA damage due to various stresses (e.g., UV irradiation, heat). Activated ATM and ATR then trigger two principal pathways leading to arrest in G_1. Step **1**: Phosphorylation of p53 stabilizes it, permitting p53-activated expression of genes encoding proteins that cause arrest in G_1, promote apoptosis, or participate in DNA repair. Step **2**: The second pathway is another way of controlling the pool of p53. The MDM2 protein in its active form can form a complex with p53, inhibiting its transcription-factor activity and causing p53 ubiquitinylation and subsequent proteasomal degradation. ATM and DNA-PK phosphorylate MDM2 to inactivate it, causing increased stabilization of p53. In addition, MDM2 levels in the cytoplasm are controlled by ATR and p14ARF (p19ARF in the mouse), sequesters it in the nucleolus, where it cannot access p53. The p14ARF gene is induced by high levels of mitogenic signaling, which are frequently observed in cells carrying oncogenic mutations in growth factor signaling pathways. The human *MDM2* gene is frequently amplified in sarcomas, which presumably causes excessive inactivation of p53. Similarly, p14ARF is also found mutated in some cancers.

Stabilized p53 also can induce expression of proteins such as Bax and PUMA that bind to and inhibit Bcl2 and thus induce apoptosis (see Figure 22-42). When cells suffer extensive DNA damage, the p53-induced expression of pro-apoptotic proteins leads to their quick elimination. While apoptosis may seem like a drastic response to DNA damage, it prevents proliferation of cells that are likely to accumulate multiple mutations. When p53 function is lost, apoptosis cannot be induced, and the accumulation of additional mutations required for cancer to develop and progress becomes more likely.

Apoptosis can be triggered in response to a number of intrinsic and extrinsic signals. For example, we will see in the next section that cytotoxic T cells can kill a target by inducing apoptosis in the targeted cell.

The Immune System Is a Second Line of Defense Against Cancer Formation

We have seen that tumor cells carry thousands of mutations, including point mutations, Indels, and chromosomal structural variants (see Figure 25-8). For a typical tumor with 5000 mutations, on average about 50 of these would lie in protein-coding sequences and thus may give rise to a protein product that was altered in some way. For tumors that arise from exposure to mutagens, such as melanomas (UV light) and lung carcinomas (tobacco smoke) the number of mutations may be hundredfold greater than this. These altered proteins are known as *neo-antigens* and would be expected to cause the tumor cell to be recognized and eliminated by the immune system in much the same way as cells that contain foreign proteins induced by infection with a pathogen such as a virus or bacterium specifically targeted for destruction.

Most precancerous cells bearing neo-antigens are thought to be efficiently eliminated by immune surveillance. Evidence for this comes from studies of immunodeficient mouse mutants, which are

more likely to acquire carcinogen-induced cancer than wild-type mice. This raises the crucial question of how did the tumors that we do see escape immune surveillance? In the following section, we discuss how the local environment within the tumor suppresses the immune system, and how monoclonal antibodies that recognize molecules enriched on the surface of tumor cells can redirect certain immune system cells to kill the tumor cell. Finally, we discuss newer ways of genetically engineering T cells of the immune system so they express on their surface monoclonal antibodies that enable these cells to recognize and kill many types of tumor cells.

The Tumor Microenvironment and Immunoediting Limit the Ability of the Immune System to Detect and Kill Established Tumors

As solid tumors develop, they recruit a variety of other cell types in addition to the cancerous cells themselves. These cells, which include fibroblasts from the organ in which the tumor develops, as well as a wide variety of different types of cells from the immune system, transform the tumor into a type of tissue, rather than simply a clone of isolated cancer cells. The non-cancer cells that surround the malignant tumor cells comprise what is called the tumor *microenvironment*. Cancer cells influence the behavior of the fibroblasts and immune cells in the microenvironment, and

conversely, cells in the tumor microenvironment influence the way the cancer cells evolve, particularly with respect to immune recognition.

During the very early stages of tumor development, inflammatory immune cells including neutrophils, macrophages, and dendritic cells respond to the presence of these abnormal tumor cells by releasing cytokine molecules that inhibit tumor cell proliferation and angiogenesis and send signals to activate various types of T cells. A particularly important class of T cells involved in killing tumor cells are called *cytotoxic T cells*; they are distinguished by the presence of the CD8 protein on their surface (see Chapter 24). To understand the mechanisms by which cytolytic T cells potentially can kill tumor cells and why this often does not occur, we must review some of the salient points by which T cells in general, and cytotoxic T cells in particular, recognize foreign molecules.

Cytotoxic T Cells Target Tumor Cells

As detailed in Chapter 24, T cells recognize not intact proteins but peptide fragments of these proteins of about 10 amino acids in length. Cells constantly degrade representative samples of all cellular proteins — whether they are made in the cell or brought in by pathogens — to peptides of this size, which are then bound to one of several two-chain glycoprotein complexes called *MHC molecules*. These MHC-peptide complexes are then transported to the cell

surface where they can be detected by passing T cells. In the case of peptides derived from mutant proteins that are displayed on the surface of the tumor cells themselves, these are generally bound to class I MHC molecules (see Figure 24-26). Because most tumor cells, like all nucleated cells in the body, express MHC class I molecules on their surface, cytotoxic T cells can directly recognize tumor cells expressing neo-antigens. However, only a small fraction of neo-antigens appear to be detected by T cells as foreign. Therefore, only tumors with a high mutational burden, such as melanomas, reach the threshold for recognition as a suitable target for destruction by immune surveillance.

Engagement of tumor cells bearing foreign tumor antigens on their MHC class I molecules by cytotoxic T cells can result in killing of the tumor cells by two different mechanisms. Some activated cytotoxic T cells release granules containing the proteins perforin and granzyme-B. Perforin and granzymes enter a target cell through endocytosis, and perforins punch holes in the endocytic vesicle membrane, allowing granzymes to enter the cytoplasm. Granzymes are serine proteases and cleave and activate apoptotic molecules within the target cells, causing programmed cell death (see Figure 24-36). Other cytotoxic T cells express on their surface FasL, a natural ligand molecule related to TNF. When FasL on the cytotoxic T cell binds to its receptor, the Fas protein on the tumor cells, an apoptotic signaling pathway in the tumor cells becomes activated, which also leads to tumor cell death. During early stages of solid tumor development, these processes effectively eliminate many of

the incipient tumor cells. As a consequence, the developing tumor and the immune system reach balance where the tumor does not grow but is not completely eliminated.

Tumor Cells Escape from Killing by Cytotoxic T Cells

Even as growth plateaus, tumor cells continue to divide in a steady state balance with immune-mediated killing. Eventually, the tumor cells may acquire additional oncogenic mutations that allow them to escape the immune system and to begin to proliferate again. This immune evasion can occur through a variety of mechanisms. In some cases, the tumor cells send signals that change the types of immune cells that are recruited into their microenvironment, so that pro-inflammatory macrophages and neutrophils are replaced with anti-inflammatory, wound-healing neutrophils and macrophages, which secrete a different set of cytokines that fail to recruit T cells into the tumor. In other cases, the tumor down-regulates the expression of class I MHC proteins, rendering the tumors invisible to cytotoxic T cells. Sometimes the tumor cells up-regulate the expression of anti-apoptotic proteins like *BCL2* that blunt the killing effects of granzymes, perforins, and FasL.

Two other mechanisms that tumor cells use to survive involve a direct attack by tumor cells on the signaling mechanisms that T cells use to kill them. In order for cytotoxic T cells to become licensed to

kill cells bearing foreign antigens, they require a second co-stimulatory activation signal in addition to recognition of peptide fragments of tumor antigens presented on class I MHC molecules (see Figure 24-35 for more detail). This second check before killing probably exists to prevent cytotoxic T cells from accidently killing normal cells and causing autoimmune injury to normal tissues. One of the best understood co-stimulatory signals comes from CD28, a cell-surface protein on T cells that binds to either of two cell-surface proteins that are on the surface of antigen-presenting cells, CD80 and CD86 (Figure 25-24, step **3**). Only when T cells see MHC-bound foreign tumor antigens and receive a signal through CD28 do they become activated for cytokine production and T-cell–mediated killing. Within a day after activation, T cells up-regulate a different cell-surface protein, CTLA-4, which competes with CD28 for binding to CD80 and CD86 and sends a negative signal that inhibits T-cell responses (Figure 25-24, step **4**). This is important because it restrains the extent of immune activation in order to limit inflammatory tissue damage. Because of the up-regulation of CTLA-4 on anti-tumor cytotoxic T cells, they become self-inhibited in killing tumor cells.

FIGURE 25-24 Overview of T-cell signaling. Activation of a T cell is initiated by the T-cell receptor (TCR), which contains one α and one β chain, each of which differs slightly in sequence in different T cells of an individual. Each αβ TCR binds to a single or group of related target peptides bound ("presented") on the surface of an MHC protein on an antigen presenting cell (step **1**). TCRs also contain signaling ζ chains as well as γ, δ, and ε chains. Binding of the TCR to a MHC-peptide complex triggers activation of the ZAP70 protein tyrosine kinase attached to the cytosolic domain of the ζ chains (step **2**); in a cytotoxic T cell this triggers a signal transduction pathway (signal 1) essential for activation of the ability of the T cell to kill the antigen-presenting cell. Activation of the T cell also requires a second signal, triggered by binding of one of several proteins on the antigen-presenting cell, predominantly CD80 or CD86, to the CD28 protein on the surface of the T cell (step **3**), triggering activation of a second signal transduction pathway that together with the first leads to activation of the T cell. Among the proteins induced during T-cell activation is CTLA-4; binding of CTLA-4 to CD80 or CD86 on the antigen-presenting cell (step **4**) activates another signaling pathway leading to inactivation of the T cell. If the antigen-presenting cell expresses on its surface either the PD-L1 or the PD-L2 protein,

these can bind to the PD-1 protein on the T cell (step **5**) and trigger a signaling pathway that induces apoptosis of the T cell, preventing it from killing the antigen-presenting cell.

A second T-cell surface receptor protein that acts as a negative regulator of T-cell function is PD-1 (*p*rogrammed *d*eath-1). PD-1 has a structure similar to CTLA-4 and when activated negatively regulates T-cell function by inducing apoptosis of activated T cells. The two ligands of PD-1, PD-L1 and PD-L2, are in the same protein family as CD80 and CD86 and are present on the surface of antigen-presenting cells; the ligands thus induce apoptosis of activated cytotoxic T cells, preventing inappropriate killing of antigen-presenting cells by T cells (Figure 25-24, step **5**). Many tumor cells overexpress PD-L1 and thus escape death from cytotoxic T cells by in effect masquerading as antigen-presenting cells.

Both the CTLA-4 pathway and the PD-1/PD-L1 signaling system are called **immune checkpoint pathways** because they normally keep the immune system in check in order to prevent the development of autoimmune diseases. Both pathways are co-opted by tumor cells in order to suppress anti-tumor immunity. This entire process in which tumor cells are initially eliminated by the immune system, reach a steady state plateau, and then eventually escape from immune control by a variety of molecular mechanisms is referred to as **immunoediting**, since the final tumor outgrowths have been shaped by its response to the innate and adaptive immune system.

Activation of the Immune System Presents a Major Opening for Cancer Therapy

As we have seen, the immune system has the capacity, largely based on activation of cytotoxic T cells, to recognize and eliminate precancerous cells, especially those that express abundant neo-antigens. We have also seen that cancer cells that are able to escape immune surveillance and continue to proliferate to form tumors have acquired the capacity to suppress killing by cytotoxic T cells. One avenue for cancer therapy is the reactivation or reengineering of the immune system to recognize and eliminate mature tumors. Here we describe two of the most promising approaches for cancer immunotherapy.

Monoclonal Antibodies Against Immune Checkpoint Molecules to Treat Cancers

One very successful method is to use antibodies that block CTLA4 from binding to CD80 and CD86 and thus prevent cytotoxic T cells from receiving inhibitory signals from CTLA-4. A CTLA-4-blocking antibody, ipilimumab, was approved for the treatment of advanced melanoma. It and similar monoclonal antibodies that block immune checkpoint activation have proven very effective in treating cancers such as melanomas that have a large mutational burden and thus have many neo-antigens recognized by many different T cells.

Monoclonal antibodies directed against either PD-L1 or PD-1 are also effective in treating several types of advanced cancers, particularly those tumors that contain many mutant proteins such as melanomas and certain lung cancers. However, when administered alone, monoclonals against CTLA-4, PD-1, or PD-L1 are effective in treating only a fraction of patients with most cancers. Increasingly, combination therapies, in which these monoclonals are combined with other antibodies and drugs are increasing the efficacy of this type of cancer immunotherapy and may eventually allow even some terminal cancer patients to survive.

Engineering T Cells to Recognize Tumor Antigens

We have just seen that cytotoxic T cells, when reactivated by inhibition of the immune checkpoint, have the capacity to recognize and kill some tumors with a large burden of mutations. However, most tumors, probably because they express an insufficient number of neo-antigens, do not respond to monoclonal antibodies to checkpoint inhibitors such as CTLA-4 or PD-1. An alternative approach is to genetically engineer T cells in the laboratory that can directly attack tumor cells bearing a marker protein on their surface and then infuse them into patients where they can perform their tumor-killing function. These T cells contain specially engineered T-cell receptors, called *c*himeric *a*ntigen *r*eceptors, and the modified cells are called **CAR T cells**. To understand how they work, we need

to first review signaling pathways that connect T-cell receptor binding to anti-tumor activity.

The cytosolic domains of the a and b subunits of the T-cell receptor do not directly activate a signal transduction pathway. Rather, binding of the extracellular TCR domain to a MHC-peptide complex triggers activation of ZAP70 protein tyrosine kinases attached to the cytosolic domains of the two adjacent ζ chains (see Figure 25-24, *bottom left*). The idea behind CARs was to engineer the T-cell receptor to trigger activation of ZAP70 in response to the presence of a tumor-specific antigen rather than the MHC-peptide complex. The first generation of CARs accomplished this by employing the antigen-binding V_H and V_L domains of a monoclonal antibody that binds to a protein enriched on the surface of a tumor cell (e.g., CD19 on a B-cell tumor) linked to the cytosolic domain of the ζ subunit through a transmembrane segment. T cells expressing such a chimeric receptor do activate ZAP70 when they encounter a tumor cell expressing the CD19 protein on its surface (Figure 25-25a), but they fail to kill the tumor cell. Realizing that this failure could be due to the absence of crucial co-stimulatory signals (signal 2 in Figure 25-24), researchers designed chimeric antigen receptors in which the cytosolic domain contained signal-transducing segments from the cytosolic domain of the ζ subunit as well as from one or more of the co-stimulatory receptors such as CD28 or 4-1BB (see Figure 25-24). In clinical trials, such CARs targeting CD19 were expressed using lentiviral vectors in normal T cells isolated from a

large number of patients with several types of human B-cell tumors (Figure 25-25b). Retransfusion of these engineered CAR T cells back into these patients in many cases led to complete remission of the cancer. Currently, researchers are developing CAR T cells expressing CARs targeting a number of proteins enriched on the surface of many types of human tumors. These are being tested against a number of malignancies for which there are presently no cures.

FIGURE 25-25 Three generations of CAR T cells. (a) Chimeric antibodies (CARs) expressed in T cells. The first generation CAR T cells to treat B-cell malignancies expressed on the T-cell surface of a chimeric protein containing the V_L and V_H transmembrane domain and the

cytosolic domain of the ζ subunit of the T-cell receptor (second panel). Recall that binding of the TCR to a peptide MHC complex normally triggers activation of the ZAP70 protein tyrosine kinase attached to the cytosolic domain of the ζ chains. Second-generation CARs contained, in addition, the cytosolic signaling domains from one of the co-stimulatory receptors that form the 4-1BB protein or the CD28 protein (see Figure 25-24). Subsequent CARs incorporated both of these co-stimulatory domains and signaling domains from other proteins as well. These co-stimulatory domains activate multiple signaling pathways that trigger rapid and extensive activation of T-cell killing of target tumor cells. (b) Generation of CAR T cells. A cDNA encoding a chimeric antibody receptor is cloned into a lentiviral vector — similar to the retrovirus vector depicted in Figure 6-35 except derived from the human HIV retrovirus. Leukapheresis, a procedure to extract T cells from a patient with a B-cell malignancy, is performed, and the T cells are infected in culture with the lentivirus vector. After culture to allow integration of the viral DNA into the genome and expression of the chimeric antibody, the T cells are transfused back to the patient. The production of CAR T cells normally takes 17–21 days.

Complications of Cancer Immunotherapy

One caveat to all of these immune-activating treatments — both monoclonal antibodies against immune checkpoint molecules and CAR T cells — is that they unleash the full force of the immune system not only against the tumor, but often against the adjacent normal tissues that are not cancerous. Consequently, a major side effect of these therapies is a *cytokine storm* that leaves the patient with potentially devastating tissue damage. Successful application of cancer immunotherapy will require finding a balance between activation of the T cells to recognize tumors with other treatments that are less injurious of normal tissues.

KEY CONCEPTS OF SECTION 25.4

Evasion of Programmed Cell Death and Immune Surveillance Processes

- Precancerous cells often have sustained DNA damage and are normally eliminated by programmed cell death or apoptosis.
- Oncogenic driver mutations that suppress apoptosis allow continued tumor cell proliferation even in the presence of sustained DNA damage.
- The most common driver oncogenic driver mutations are in p53, a transcription factor that activates the expression of genes for cell cycle arrest or apoptosis. Cancer cells that have loss of function mutations in p53 continue to proliferate damage to their genomes and thus have a propensity to accumulate mutations.
- Immune cells in the tumor microenvironment detect mutant proteins and shape the developing tumor through a three-step process involving tumor cell elimination, equilibrium between the tumor cells and the immune system, and late escape of tumor cells from immune control.
- Cytotoxic T cells recognize fragments of mutant proteins presented by MHC proteins on the surface of tumor cells. However, the killing activity of the T cells is usually abated in part because of activation of inhibitory receptors on the T-cell surface, such as CTLA4 and PD-1.
- Monoclonal antibodies to CTLA4 and PD-1 and to PD-L1, the ligand of PD-1, prevent activation of these inhibitory receptors and enhance the ability of the T cells to kill the tumor cells. These monoclonals are used to treat cancers such as melanomas in which many mutations have accumulated.
- CAR T cells are normal T cells in which lentivirus vectors have been used to introduce a chimeric protein, a CAR, containing the V_H and V_L domains of a monoclonal antibody targeting a protein on the surface of a tumor cell, a transmembrane segment, and cytosolic domains from the TCR ζ submit and from any of several co-stimulatory receptors. CAR T cells are efficacious in killing many types of human tumors and in curing the cancer.

tumor suppressor gene
Warburg effect

Review the Concepts

1. Despite differences in origin, cancer cells have several features in common that differentiate them from normal cells. Describe these.

2. What characteristics distinguish benign from malignant tumors?
3. Which important characteristic of tumor cells did Otto Warburg discover?
4. Because of oxygen and nutrient requirements, cells in a tissue must reside within 100 μm of a blood vessel. Based on this information, explain why many malignant tumors often possess gain-of-function mutations in one of the following genes: β*FGF*, *TGF*-α, and *VEGF*.
5. Ninety percent of cancer deaths are caused by metastatic rather than primary tumors. Define *metastasis.* Explain the rationale for the use of the cancer treatment agent batimastat, an inhibitor of matrix metalloproteases and of the plasminogen activator receptor.
6. What is the importance of the EMT during metastasis?
7. What hypothesis explains the observations that incidence of human cancers increases exponentially with age? Give an example of data that confirm the hypothesis.
8. Distinguish between proto-oncogenes and tumor suppressor genes. To become cancer promoting, do proto-oncogenes and tumor-suppressor genes undergo gain-of-function or loss-of-function mutations? Classify the following genes as proto-oncogenes or tumor-suppressor genes: *p53, ras, BCL-2, JUN, MDM2*, and *p16*.
9. Describe how mutations in genome maintenance factors promote tumorigenesis. Why would inactivation of a mismatch repair gene cause colon cancer?

10. Hereditary retinoblastoma generally affects children in both eyes, while spontaneous retinoblastoma usually occurs during adulthood only in one eye. Explain the genetic basis for the epidemiological distinction between these two forms of retinoblastoma. Explain the apparent paradox: loss-of-function mutations in tumor-suppressor genes act recessively, yet hereditary retinoblastoma is inherited as an autosomal dominant.
11. Explain the concept of loss of heterozygosity (LOH). Why do most cancer cells exhibit LOH of one or more genes? How does failure of the spindle assembly checkpoint lead to loss of heterozygosity?
12. Many malignant tumors are characterized by the activation of one or more growth-factor receptors. What is the catalytic activity associated with transmembrane growth-factor receptors such as the EGF receptor? Describe how a point mutation that converts a valine to glutamine within the transmembrane region of the HER2 receptor leads to activation of the relevant growth-factor receptor.
13. Describe the common signal transduction event that is perturbed by cancer-promoting mutations in the genes encoding RAS and NF1. Why are mutations in *RAS* more commonly found in cancers than mutations in *NF1*?
14. Describe the mutational event that produces the *MYC* oncogene in Burkitt's lymphoma. Why does the particular mechanism for generating oncogenic *MYC* result in a lymphoma rather than another type of cancer? Describe another mechanism for generating oncogenic *MYC*.

15. Pancreatic cancers often possess loss-of-function mutations in the gene that encodes the Smad4 protein. How does this mutation promote the loss of growth inhibition and highly metastatic phenotype seen in pancreatic tumors?
16. Why are mutations in the p16-arf-p15 locus so dangerous?
17. Explain how epigenetic changes can contribute to tumorigenesis.
18. Several strains of human papilloma virus (HPV) can cause cervical cancer. How does the viral E7 protein contribute to host cell transformation?
19. Loss of p53 function occurs in the majority of human tumors. Name two ways in which loss of p53 function contributes to a malignant phenotype. Explain how the carcinogen benzo(*a*)pyrene can cause loss of p53 function.
20. The active form of p53 is a tetramer of four identical subunits. However, a mutant version of just one subunit can inactivate the entire tetramer. Explain how this dominant negative interaction increases the probability that mutations in p53 are selected for during cancer progression.
21. Explain why only about 1 percent of mutations in a tumor cell have an effect on a cellular protein and thus may cause production of a neo-antigen.
22. CAR T cells are genetically engineered to kill cancer cells by introduction of a chimeric protein composed of the antigen-binding domain of a monoclonal antibody linked to the cytosolic ζ subunit of the T-cell receptor. Explain the

function in targeting and killing cancer cells of the antibody part and the T-cell receptor part of the chimeric protein.

    hydrolysis of, 693–694, 693f
    neurotransmitters, release of, 1070
    release from ER triggered by IP_3, 694–695, 695f
    rise in, cellular responses to, 692t
    as second messengers, 692–697
    skeletal muscle contraction, regulation of, 782–783, 783f
    store-operated channel in plasma membrane, 695–696, 696f
Ca^{2+} pump, mechanism of action, 483–484
CAD domains, 696
Cadherin, 904, 904f, 913–918, 914f, 917f
Caenorhabditis elegans, 902, 991
Cajal bodies, 438, 439f
Calcium, 108, 109f, 1072f
Calcium signaling, 530
Callose, 955

Calmodulin, 108, 109f, 165f, 483, 686
Calnexin, 598, 599, 601f, 692
Calorie, 61
Calreticulin, 598, 599, 601f, 692
Calvin cycle, 570–573
Cambrian explosion, 520
cAMP
    activates protein kinase A, 683–685, 685f, 687–689
    cellular responses to rise in, 688t
    extracellular signaling, amplification of, 687f
    glycogen metabolism, regulation of, 686f
    in glycogenolysis, 697, 697f
    levels of, 690f
cAMP-dependent protein kinase, 684
cAMP-response element (CRE), 688
Campylobacter jejuni, 491, 492f
Cancer
    aerobic glycolysis, 1153–1154, 1154f
    age and, 1173f
    breast, 146, 195, 672, 1153f, 1159, 1159t, 1176–1177
    causative mutations, 260
    cervical, 224
    colon, 1152f, 1159t, 1173–1174, 1175f
    common mutations, 1166t
    diagnosis, 1176–1177
    evolutionary progression of, 1150f
    genetic and genomic basis of, 1157–1168
        carcinogens, 1157–1158

epigenetic changes, 1167–1168
familial syndromes, 1158–1159, 1159t
genome sequencing, 1160, 1161f
inherited predispositions, 1163–1164
microRNAs and, 1166–1167
oncogenes, 1160–1161
oncogenic drivers, 1162–1165, 1165f
somatic mutations, 1159–1160
tumor suppressor genes, 1165–1166
immune system, activation of, 1181–1183
immune system and, 1146–1147
immunotherapy, 1147
lung, 1158
melanomas, 193, 1181
mTOR pathway mutations, 969
overview of, 1149–1151
programmed cell death, evasion of
immune system and, 1179
oncogenic driver mutations, 1177–1178
p53 protein, 1178–1179
tumor microenvironment and immunoediting, 1179–1181
skin, 193
somatic mutations, 1146–1147
targeted therapy, 1162–1163
TGF-β signaling and, 737
treatments for, 1176–1177, 1181–1183
tumor cells vs. normal cells, 1151–1156
tumorigenesis, 1168–1177

animal models, 1174–1176, 1176f
colon cancers, 1173–1174, 1175f
growth control pathways, 1170–1171
molecular cell biology, 1176–1177
multi-hit model, experimental reconstruction of, 1172–1173
nuclear transcription factors, 1171–1172
receptor mutations, 1168–1169, 1169f
signaling pathways, aberrations in, 1172
signal-transducing proteins, 1169–1170
types of, 1149
Cancer stem cell, 1154
Capacitors, 494
Capping proteins, 762–763, 762f

Exoplasmic leaflets, 452–453
Exoplasmic side, 540, 543f
Exoribonucleases, 433f
Exosome, 409–410, 409f
Exothermic reactions, 62
Exportin, 162, 163f
Exportin 1, 618
Exportin 5, 420
Expressed sequence tag (EST), 249
Extended closed conformation, 944, 945f
Extended open conformation, 944, 945f
Extensin, 953
External face, 446
External signal, 671f
Extracellular cues, 894
Extracellular domain (ECD), 709–711, 710f, 711f
Extracellular matrix (ECM), 27, 143, 143f, 663, 733–735, 902

adhesion, signaling, and other functions, 905–908
basal lamina, 926–932
functions of, 927–928, 927f
laminin, role of, 928, 929f
major protein components of, 928f
perlecan, 931–932
sheet-forming type IV collagen, 928–931, 931f
cell density in, 907f
connective tissue, 932–942
elastic fibers, 941–942, 941f
fibrillar collagens, 932–934, 933f, 934f
fibronectins, 938–941, 939f, 940f
hyaluronan, 937–938
metalloproteases, 942
proteoglycans, 935–937, 935f, 938f
type I and type II collagens, 934–935
defective skeletal development and, 908f
functions of, 907t
hippo kinase cascade pathway, regulation of, 984–985, 985f
muscular dystrophy and, 948–949, 948f
proteins, 906t
Extracellular signaling, 663f, 868–869
Extracellular signaling molecules, 661, 705f
Extravasation, 950, 950f, 1139, 1156
Extrinsic hormonal signals, 1004
Eyeless, 31, 31f
Eyepiece, 150
Eyespot, 1063

Ezrin, 772f

F_1 ATPase, 553
Fab domain, 768
Facilitated diffusion, 473
Facilitated transport, 473, 474–480
Facilitated transporters, 473
F-actin, 757–758, 758f, 771f
F-actin polymers, 756–757, 757f
Facultative anaerobes, 518
FAD (flavin adenine dinucleotide), 66–67, 66f, 67f, 102
$FADH_2$, oxidation of, 537
Familial adenomatous polyposis (FAP), 1174
Familial hypercholesterolemia (FH), 651
Families, 81
Fanconi anemia, 1159t
Fas ligand, 1039
Fatty acid-binding proteins (FABPs), 464–465, 465f
Fatty acids, 51–52
    biosynthesis, 970
    double bonds and, 54f
    enzymes and, 464
    essential, 52
    movement, cytosolic proteins and, 464–465

oxidation of, 531–537, 532f
peroxisomal oxidation of, 536, 536f
in phospholipids, 52t
phospholipids, incorporation into, 465
polyunsaturated, 52
saturated, 52
unsaturated, 52, 464, 970–972
Fatty acyl group, 52
Fatty acyl-CoA dehydrogenase, 542
Fc domain, 768
Fc receptor (FcR), 768, 1108
F-class pumps, 480–481, 481f
Feedback circuits, 1048f
Feedback inhibition, 107
Feedback loops, 696, 697f, 737–738, 857f, 865, 876, 877f
Feedback mechanisms, 689–691, 721–722
Feedback repression, 669–670, 689, 959
Feed-forward activation, 518
Fermentation, 518, 519f
Fertilization, 991, 992
Fetal aneuploidy, 898f
FG-nucleoporin, 614–616, 615f
FH1 domain, 763
FH2 domain, 763, 764f
Fibril-associated collagens, 930t, 932, 934f
Fibrillar adhesions, 943
Fibrillar collagen, 930t, 932–934, 933f, 934f
Fibrillin-1 gene, 941

Fibrils, 94f, 95, 932, 933–934, 935
Fibroblast, 140, 204f, 262, 262f, 309f, 932, 939
Fibroblast growth factor (FGF), 709, 710, 710f, 716f
Fibronectin
alternative splicing, 204, 204f
antibodies, 908f
cell-binding region of, 940f
exons and, 280
functions of, 938–941
multi-adhesive matrix proteins, 904f, 906, 906t, 927
organization of, 939f
Fibrous proteins, 82
Fibulins, 928
Fight-or-flight response, 683, 685
Filamin, 770
Filopodia, 755, 788
Fimbrin, 770
Fingerprint, DNA, 277, 287–288, 288f
First polar body, 854f
Fischer, Emil, 98
Fiske, Cyrus, 64
Fission (mitochondrial), 527–529, 528f
Fission yeast, 852

Free energy reactions, 100f
Free-energy change (ΔG), 61–63, 62f
FRET biosensor, 160, 162, 162f
Frizzled (Fz), 741, 1025
Frontal lobe, 1043f, 1044
Fructose 2,6-bisphosphate, 517f, 518
Fruit flies, 232–233
Functional complementation, 240–241, 242f
Functional domains, 79, 345, 346f
Functional light-chain gene, 1109–1111

Functional mRNA, 202–204, 203f
Functional RNAs, 284, 285f
Fungi, 852
Fura-2, 152
Furin, 647
Fusion (mitochondrial), 527–529, 528f
Fusion proteins, 371f

G

G protein–coupled receptor (GPCR), 661f, 662, 676–682, 1083–1084, 1083f
adenylyl cyclase, activation or inhibition of, 683–691, 683f
anchoring proteins, 688–689
cAMP activates protein kinase A, 683–685
cAMP-mediated activation of PKA, 687–688, 687f
feedback mechanisms, 689–691
gene transcription, activation of, 688, 689f
hormone-induced, 684f
PKA, hormone-induced activation, 685–687, 685f, 686f
receptor-ligand complexes, 683
signal amplification, 687
β_2-adrenergic receptor, 678f
binding of β-arrestin to, 691f
in cell adhesion, 904
classes of, 677f
effector proteins, regulation of, 681
exchange of GTP to GDP, 679–681, 680f, 681f

glucagon receptor, 679f
human hormones, identification of, 681–682
pharmaceutical importance, 677t
structure of, 676–678, 676f
G_1 cyclin-CDK, 857
G_1 phase, 21, 849
G_1/S phase cyclin-CDK, 857
G_2 phase, 21, 849–850
G-actin, 758
G-actin monomers, 756–757, 757f, 759f, 760f
Gain-of-function mutations, 1166f
GAL4 gene, 345, 346f
Galactose, 501–503, 502f

in translation, 423
tripartite, 1066f
Synapsins, 1070
Synapsis, 230f, 894
Synaptic cleft, 1046f, 1137
Synaptic plasticity, 1042, 1086, 1088–1090, 1089f
Synaptic vesicles, 1045, 1066f, 1070–1073, 1071f, 1072f

Synaptonemal complex (SC), 894
Synaptotagmin, 1072
Synchronous signals, 1044
Syndecans, 937
Synechococcus elongatus, 980f–981f, 981
Synonymous codons, 206
Synonymous mutation, 207
Syntaxin, 635
Syntelic attachment, 881
Synteny, 28, 29f, 314
Synthetic lethal mutations, 235–236, 236f
Szostak, Jack, 318

T

T cells, 142, 142f, 1095, 1096f, 1181–1182
    activation, signals required for, 1136–1137, 1136f
    B cells, collaboration with, 1143–1145, 1144f
    CD8 co-receptor, 1137, 1137f
    cytokines, secretion of, 1138
    cytotoxic, 1137, 1137f
    development of, compared to B cells, 1135f
    MHC molecules, recognition of, 1134–1135
    proliferation and differentiation, 1132–1134, 1133f
Tagging, 267, 267f
Tail domain, 774, 811
Tail-anchored proteins, 590–591, 591f
Talin, 910, 946f–947f

Tamoxifen, 1176
Tandemly repeated arrays, 284
Tangles, 95
Taq polymerase, 244, 244f
Tardigrades, 1f
Target (destination) organelles, 629
Target cell, 662
Target field, 1032
Targeted fluorescent proteins, 674–675
Targeted therapy, 1162–1163
Targeting sequences, 578t, 579, 607f
Taste, sense of, 1080–1083, 1082f
Taste buds, 1080–1083
Taste receptors, 1081
Tat, 339, 340f
Tat (twin-arginine translocation) pathway, 611
TATA box, 334, 342, 342f, 357
TATA box-binding protein (TBP), 182f, 336
Taxol, 270, 805
Tay-Sachs disease, 254t
T-cell help, 1117
T-cell receptor (TCR), 1129, 1130f, 1131f
    similarity to immunoglobulin genes, 1131–1132
    structure of, 1129–1130
    variable residues, encoding of, 1132
T-cell signaling, 1180f
Telocytes, 1007–1008
Telomerase, 319–321, 321f, 1153

Telomere, 318, 354–355, 356f
Telomere (TEL) sequences, 318, 319f
Telomere terminal transferase, 320–321
Telomeric heterochromatin, 356f
Telomeric sequences, 319–321
Telophase, 827f, 828, 887f
Temperature, elevated, 976–978, 977f
Temperature-sensitive mutation, 25, 232, 233f, 852
Template, 185–186, 200
Temporal lobe, 1043f, 1044
Terminal deoxynucleotidyl transferase (TdT), 1112
Termination, 323
Termination codon, 206
Termination stage of transcription, 201f, 202
Termination stage of translation, 216–217, 216f
Ternary complex factor (TCF), 720
Tertiary structure, 72f, 77, 80f
Testants, 1075
Tetrahedral intermediate, 101f
Tetrahymena thermophila, 436
Tetraspanins, 920
TFIIB recognition element (BRE), 334
TGF-β family of growth factors, 733–738
    binding and activating signal transduction, 735
    latency and activation, 734f
    negative feedback loops, 737–738
    Smad transcription factors and, 735–737, 736f
    storage of in extracellular matrix, 733–735

TGF-β receptor family, 733, 735, 735f, 737
TGF-β receptor kinases, 735f
TGF-β signaling, 1173f
Thalassemia, 415
Thermal energy, 60
Thermus aquaticus, 244, 582, 582f
Thick filaments, 774, 780, 781f, 782f
Thick-filament regulation, 785
Thin filaments, 780, 781f, 782f, 783f
Thin sections, 168–169, 169f
Thin-filament regulation, 782
Thioredoxin (Tx), 570
Thompson, D'Arcy, 72
3-Hydroxyproline, 48f
Three Na^+/one-Ca^{2+} antiporter, 504
3′ cleavage/polyadenylation, 387, 398–399, 398f
3′ end, 180, 180f, 185–186
3′ → 5′ direction, 186, 186f
3-D adhesions, 943, 944
Threonine, 47, 668f
Threshold potential, 1076
Thrombopoietin, 727
Thrombospondin (TSP), 1065
Thylakoid lumen, 559
Thylakoid membranes, 559–560, 560f, 561, 562f
Thylakoids, 21, 559, 560f, 602, 610–611, 610f
Thymically derived regulator T cells (Treg), 1136
Thymidine, 124

Thymine, 48, 49, 180
Thymine-thymine dimers, 193, 194f, 195f
Thymocytes, 1125
Thymosin-β_4, 762
Thymus, 1125, 1135–1136
Tic complex, 609
Tight junction, 507, 508, 911, 912, 913t, 920f, 921f, 922f
    in blood-brain barrier, 1048
    composition of, 921f
    functions of, 912f, 913, 920–923, 920f, 922f
Time-of-flight (TOF) instruments, 126, 126f
TIMPs (tissue inhibitors of metalloproteinases), 942
+TIPS (plus-end tracking proteins), 807, 808f
TIRF microscopy, 158, 160f
Tissue culture, 855
Tissues, 901–956
    adhesive interactions in motile and nonmotile cells, 943–951
    basal lamina, 926–932
    cell-cell and cell–extracellular matrix adhesion, 903–910
    cell-cell and cell–extracellular matrix junctions and adhesion molecules, 911–926
    connective tissue, 932–942
    integrating cells into, 901–903
    in plants, 951–956
Titin gene, 280
Titin protein, 782
Titration curve, 59, 59f
TNF receptor-associated death domain protein (TRADD), 1039

Tolerance, 1094, 1095
Toll-like receptors (TLR), 747, 749f, 1098, 1099f, 1140–1143, 1141f
Tomogram, 170
Topogenic sequence, 587, 592f
Topoisomerase I, 184, 184f, 189
Topoisomerase II, 184
Topological domains, 79–80, 309–311
Topologically associated domains (TADs), 874f
Topology, 460, 587, 588–591, 589f, 590f, 593–594
TOR pathway, 424, 964–965
Torsional stress, 184, 184f
Total internal reflection fluorescence (TIRF) microscopy, 158, 160f
Totipotent, 991, 992
Toxins, 487–490, 769
TRAF6, 749
TRAMP complex, 410
Trans (intercellular) interactions, 905
Trans configuration, 87, 88, 88f
Trans fats, 53
Transcellular pathway, 921
Transcellular transport, 507–510, 922f
    bone resorption, 509–510, 509f
    of glucose and amino acids, 507–508, 508f
    rehydration therapy, 508
    stomach contents, acidification of, 508–509, 509f
Transcription, 11, 11f, 178, 179f, 199–205
    activation of, 688, 689f
    activators, 345, 346f

definition of, 87, 199
divergent, 335–336
epigenetic regulation, 372–380
DNA methylation, 372–373
long noncoding RNAs, 377–379
methylation of specific histone lysines, 373–375
by polycomb and trithorax complexes, 375–377
in eukaryotic genomes, 280–282, 327–333
carboxy-terminal domain, 332–333
clamp domain, 331–332
nuclear RNA polymerases, 329–331
regulation of, 342–343
regulatory elements, 327–329
induction of, 721f
initiation of, 361–365
nonhistone proteins and, 311–312
other eukaryotic systems, 380–382
Pol I, 380–381
Pol III, 381–382
regulation of, 324, 324f, 326f
activation and repression domains, 349–350
repression and activation
activators and histone acetylation, 358
bursts, 365
chromatin-remodeling complexes, 358–359
heterochromatin and, 354–355
Mediator, 359–361
molecular mechanisms of, 354–366

pioneer transcription factors, 359
repressors and histone deacetylation, 355–358
transcriptional condensates, 361–365
by RNA polymerase I, 380–381, 380f
by RNA polymerase III, 381–382, 381f
stages of, 201–202, 201f
termination of, 371
Transcription bubble, 201
Transcription factors
activation of, 730
activators and, 346f
activity, regulation of, 366–372
cellular differentiation, 366–368
hormones binding to nuclear receptors, 369–370
metazoans, 370–371
nuclear receptors, 368–370
termination of transcription, 371
AU-rich elements and, 419
definition of, 11
induction of a particular gene, 708f
interphases chromatins and, 311
MAP kinase and, 720–721
master set of, 29–30
mutations, 325f
NF-κB, 747–748, 748f
in Notch/Delta pathway, 738–740
in nuclear-receptor superfamily, 369f
oxygen-sensitive, 974–975, 975f

pioneer, 359
proteins, evaluation of, 345f
regulation of protein-coding genes, 350–352
in secondary structures, 76
Smads, 733–738
template DNA to complement RNA, 200–202
TGF-β/Smad signaling pathway, 735–737, 736f
transcription, regulation of, 178, 324, 326f, 327, 343
Wnt signaling and, 741–742
Transcription initiation complex, 84f
Transcription start sites (TSS), 335–336, 341, 363f
Transcription unit, 280, 282f
Transcriptional (mRNA) profiling, 133
Transcriptional activation, 863–865, 864f
Transcriptional condensates, 361–365
Transcriptional memory, 366
Transcriptional network, 996f
Transcription-control elements, 340, 341f, 342f
Transcription-control region, 324, 327–328, 328f, 333
Transcytosis, 649, 1023, 1105, 1105f
Transducin, 699, 702–703, 702f
Transduction, 664
Transepithelial resistance, 922
Transepithelial transport, 922f
Transesterification, 391–393, 392f
Transfection, 265
Transfer RNA (tRNA), 178, 179f, 205–210
amino acid links, 209–210

folded structure of, 207–208
nonstandard base pairing, 208–209
processing of, 431–438
roles of in protein synthesis, 205, 205f, 207–208, 208f
structure of, 209f
synthesis of, 966
Transferrin, 425
Transformation, 239, 265–266, 1161
Transformed cells, 140
Transformer genes, 403–404
Transforming growth factor (TGF-β), 733
***trans*-Golgi network**
definition of, 625
enzymes, trafficking of, 646f
functions of, 626, 629f, 630, 639, 640–641
N-linked oligosaccharides and, 640f
protein aggregation in, 645–647
in secretory and endocytic pathways, 624f
vesicle-mediated protein trafficking, 642f, 643
Transient dipoles, 41–42
Transient receptor potential (TRP) channels, 909
Transient transfection, 265, 265f
Transit amplifying cells, 1003, 1003f
Transition state, 63, 97, 100f
Transitional epithelia, 911f
Transition-state intermediate, 63
Translation, 10, 87, 178
cytoplasmic polyadenylation and, 422–423, 423f

efficiency of, 217–218, 217f
initiation of, 213, 214f, 582
polypeptide passage through translocon, 582–585
regulation of
sequence-specific RNA-binding proteins and, 424–426
surveillance mechanisms, 426–428, 426f, 427f
simultaneous translocation, 581f
termination of, 216–217
Translesion polymerase, 193
Translocation, 215, 579–580, 581–582, 581f, 583f, 610–611
Translocation channel, 579
Translocon, 582–585, 584f
Transmembrane AMPA receptor regulatory proteins (TARPs), 1090
Transmembrane channels, 555
Transmembrane collagens, 930t, 933
Transmembrane domain (TMD), 711f
Transmembrane electric gradient, 494–495, 495f
Transmembrane proteins. *See also* Integral membrane proteins
alpha (α) helix, 455–458, 456f, 457f
orientation in bilayer, 460–461
Transmembrane transport, 470–510
antiporters, cotransport by, 500–507
ATP-powered pumps, 480–484
Ca^{2+} pump mechanism of action, 483–484
classes of, 480–482, 481f
ionic gradients, 482

Glossary

Boldface terms within a definition are also defined in this glossary.

Figures and tables that illustrate defined terms are noted in parentheses.

AAA ATPase family
A group of proteins that couple hydrolysis of ATP with large molecular movements usually associated with unfolding of protein substrates or the disassembly of multisubunit protein complexes.

ABC superfamily
A large group of integral membrane proteins that often function as ATP-powered **membrane transport proteins** to move diverse molecules (e.g., phospholipids, cholesterol, sugars, ions, peptides) across cellular membranes. (Figure 11-15)

acetyl CoA
Small, water-soluble metabolite comprising an acetyl group linked to coenzyme A (CoA). The acetyl group is transferred to citrate in the **citric acid cycle** and is used as a carbon source in the synthesis of fatty acids, steroids, and other molecules. (Figure 12-12)

acetylcholine (ACh)
Neurotransmitter that functions at vertebrate neuromuscular junctions and at various neuron-neuron synapses in the brain and peripheral nervous system. (Figure 22-26)

acid
Any compound that can donate a proton (H^+). The carboxyl and phosphate groups are the primary acidic groups in biological macromolecules.

actin
Abundant structural protein in eukaryotic cells that interacts with many other proteins. The monomeric globular form (*G-actin*) polymerizes to form actin filaments (*F-actin*). In muscle cells, F-actin interacts with **myosin** during contraction. See also **microfilament**. (Figure 17-5)

actin cross-linking proteins
Proteins in a vertebrate cell that assemble actin filaments into organized structures.

action potential
Rapid, transient, all-or-none electrical activity propagated in the plasma membrane of excitable cells (e.g., neurons and muscle cells) as the result of the selective opening and closing of voltage-gated Na^+ and K^+ channels. (Figures 23-2 and 23-9)

activation domain
A region of an activator transcription factor that will stimulate transcription when fused to a DNA-binding domain.

activation energy
The input of energy required to (overcome the barrier to) initiate a chemical reaction. By reducing the activation energy, an **enzyme** increases the rate of a reaction. (Figure 2-30)

activation loop
A region in most protein-tyrosine kinases, containing a tyrosine residue that, when phosphorylated, increases kinase activity.

activator
Specific **transcription factor** that stimulates transcription.

active site
Specific region of an enzyme that binds a **substrate** molecule(s) and promotes a chemical change in the bound substrate. (Figure 3-24)

active transport
Protein-mediated movement of an ion or small molecule across a membrane against its concentration gradient or electrochemical gradient driven by the coupled hydrolysis of ATP. (Figure 11-3, **[1]**; Table 11-1)

adapter proteins
Adapter proteins physically link one protein to another protein by binding to both of them. Adapter proteins directly or indirectly (via additional adapters) connect cell-adhesion molecules or adhesion receptors to elements of the cytoskeleton or to intracellular signaling proteins.

adapter protein (AP) complexes
Heterotetrameric protein complexes mediate intracellular membrane trafficking along endocytic and secretory transport pathways. Three different AP complexes are known (AP1, AP2, and AP3), each with four subunits of different, though related, proteins.

adenosine triphosphate (ATP)

A nucleotide that is the most important molecule for capturing and transferring free energy in cells. Hydrolysis of each of the two phosphoanhydride bonds in ATP releases a large amount of free energy that can be used to drive energy-requiring cellular processes. (Figure 2-31)

adenylyl cyclase
One of several enzymes that is activated by binding of certain ligands to their cell-surface receptors and catalyzes formation of cyclic AMP (cAMP) from ATP; also called *adenylate cyclase*. (Figure 15-20)

adherens junction
A type of anchoring junction that connects the lateral membranes of adjacent epithelial cells and is usually located near the apical surface, just below the tight junction. (Figure 20-11)

adhesion receptor
Protein in the plasma membrane of animal cells that binds components of the **extracellular matrix**, thereby mediating cell-matrix adhesion. The **integrins** are major adhesion receptors. (Figure 20-1, **[5]**)

ADP (adenosine diphosphate)
The product, along with inorganic phosphate, of ATP hydrolysis by ATPases.

aerobic
Referring to a cell, organism, or metabolic process that utilizes gaseous oxygen (O_2) or that can grow in the presence of O_2.

aerobic oxidation
Oxygen-requiring metabolism of sugars and fatty acids to CO_2 and H_2O coupled to the synthesis of ATP.

aerobic respiration
See **aerobic oxidation**.

afferent neurons
Nerves that transmit signals from peripheral tissues to the central nervous system.

agonist
A molecule, often synthetic, that mimics the biological function of a natural molecule (e.g., a hormone).

Agrin

A glycoprotein synthesized by developing motor neurons that increases MuSK kinase activity in a muscle cell, facilitating development of a neuromuscular junction. (Figure 23-24)

Akt
A cytosolic serine/threonine kinase that is activated following binding to PI 3,4-bisphosphate and PI 3,4,5-trisphosphate; also called *protein kinase B*.

allele
One of two or more alternative forms of a gene. Diploid cells contain two alleles of each gene, located at the corresponding site (locus) on **homologous chromosomes**.

allostery
Change in the tertiary and/or quaternary structure of a protein induced by binding of a small molecule to a specific regulatory site, causing a change in the protein's activity.

alpha carbon atom (C*α*)
In amino acids, the central carbon atom that is bonded to four different chemical groups (except in glycine) including the side chain, or R group. (Figure 2-4)

alpha α helix
Common protein **secondary structure** in which the linear sequence of amino acids is folded into a right-handed spiral stabilized by hydrogen bonds between carboxyl and amide groups in the backbone. (Figure 3-4)

alternative splice site
The specific site at which splicing takes place during the processing of pre-mRNA into mature mRNA. ~95 percent of mammalian mRNAs are processed from primary transcripts that are alternatively spliced into more than one type of mRNA, often in a cell-type-specific manner.

alternative splicing (alternative RNA splicing)
Process by which the exons of one pre-mRNA are spliced together in different combinations, generating two or more different, mature mRNAs from a single pre-mRNA. (Figure 5-28)

amino acid
An organic compound containing at least one amino group and one carboxyl group. In the amino acids that are the **monomers** for building proteins, an amino group and carboxyl group are linked to a central carbon atom, the α carbon, to which a variable side chain is attached. (Figures 2-4 and 2-14)

aminoacyl-tRNA
Activated form of an amino acid, used in protein synthesis, consisting of an amino acid linked via a high-energy ester bond to the 3′-hydroxyl group of a **tRNA** molecule. (Figure 5-31)

amphipathic (or amphiphilic)
Referring to a molecule or structure that has both a **hydrophobic** and a **hydrophilic** part.

amphitelic attachment
Describes the correct attachment of chromosomes to the mitotic spindle, where sister kinetochores attach to microtubules emanating from opposite poles. (Figure 19-25)

anaphase
Mitotic stage during which the **sister chromatids** (or duplicated homologs in meiosis I) separate and move apart (segregate) toward the spindle poles. (Figures 18-38 and 18-39)

anchoring junctions
Specialized regions on the cell surface containing **cell-adhesion molecules** or **adhesion receptors**; includes *adherens junctions* and **desmosomes**, which mediate cell-cell adhesion, and *hemidesmosomes*, which mediate cell-matrix adhesion. (Figures 20-14 and 20-16)

anaerobic respiration
Respiration in which molecules other than oxygen, such as sulfate or nitrate, are used as the final recipient of the electrons transported via the electron-transport chain.

anaphase-promoting complex (cyclosome; APC/C)
A ubiquitin ligase that targets securin, mitotic cyclins, and other proteins for proteasomal degradation from the onset of anaphase until entry into the subsequent cell cycle.

aneuploidy
Any deviation from the normal diploid number of chromosomes in which extra copies of one or more chromosomes are present or one of the normal copies is missing.

angiogenesis
The developmental process for the formation of blood vessels that are needed to supply nutrients to a growing tumor.

anion
A negatively charged ion.

antagonist

A molecule, often synthetic, that blocks the biological function of a natural molecule (e.g., hormone).

anterograde
Vesicular trafficking in the direction of ER to plasma membrane.

antibody
A protein (immunoglobulin), normally produced in response to an **antigen**, that interacts with a particular site (**epitope**) on the same antigen and facilitates its clearance from the body. (Figure 3-22)

anticodon
Sequence of three nucleotides in a tRNA that is complementary to a **codon** in an mRNA. During protein synthesis, base pairing between a codon and anticodon aligns the tRNA carrying the corresponding amino acid for addition to the growing polypeptide chain. (Figure 5-32)

antigen
Any material (usually foreign) that elicits an immune response. For B cells, an antigen elicits formation of antibody that specifically binds the same antigen; for T cells, an antigen elicits a proliferative response, followed by production of **cytokines** or the activation of cytotoxic activity.

antigen-presenting cell (APC)
Any cell that can digest an antigen into small peptides and display the peptides in association with class II MHC molecules on the cell surface where they can be recognized by T cells. *Professional* APCs (dendritic cells, macrophages, and B cells) constitutively express class II MHC molecules. (Figures 24-26 and 24-28)

antigen processing and presentation
The sequence of events by which a protein capable of eliciting an immune response is converted into peptides, presented by products of the major histocompatibility complex for display at the cell surface.

antiport
A type of **cotransport** in which a membrane protein (*antiporter*) transports two different molecules or ions across a cell membrane in opposite directions. See also **symport**. (Figure 11-3, **[2C]**)

antiporter

An integral membrane protein that functions as a cotransporter to transport two molecules in opposite directions across a membrane.

apical
Referring to the tip (apex) of a cell, an organ, or other body structure. In the case of epithelial cells, the apical surface is exposed to the exterior of the body or to an internal open space (e.g., intestinal lumen, duct). (Figure 20-10)

Apicomplexa
A large family of unicellular parasitic organisms; many cause human diseases such as malaria and toxoplasmosis.

apoptosis
A genetically regulated process, occurring in specific tissues during development and disease, by which a cell destroys itself; marked by the breakdown of most cell components and a series of well-defined morphological changes; also called *programmed cell death.* See also **caspases**. (Figures 22-34 and 22-42)

aquaporins
A family of **membrane transport proteins** that allow water and a few other small uncharged molecules, such as glycerol, to cross biomembranes. (Figure 11-8)

ARF protein
A family of small GTPases that trigger the assembly of vesicles coated with COPI or clathrin-AP complexes.

Argonaute protein
A multidomain member of a protein family with a recognizable conserved sequence. Several Argonaute proteins are expressed in some organisms, especially plants, and are found in distinct **RISCs** with different functions. Humans express four Argonaute proteins.

Arp2/3 complex
A complex of seven proteins, including two actin-related proteins, able to nucleate the assembly of actin filaments when stimulated by F-actin and a nucleation promoting factor (NPF).

aster
Structure composed of microtubules (astral fibers) that radiate outward from a **centrosome** during mitosis. (Figures 18-38 and 18-39)

astrocytes

Star-shaped glial cells in the brain and spinal cord that perform many functions, including support of endothelial cells that form the blood-brain barrier, maintain extracellular ion composition, and provide nutrients to neurons.

asymmetric cell division
Any cell division in which the two daughter cells receive the same genes but otherwise inherit different components (e.g., mRNAs, proteins) from the parental cell. (Figure 22-24b)

ataxia telangiectasia and Rad3-related protein (ATR)
One of a pair of homologous protein kinases, together with **ataxia telangiectasia mutated (ATM)**, that is central for DNA damage signaling and repair. A related protein kinase called **DNA-PK** is also critical.

ataxia telangiectasia mutated (ATM)
One of a pair of homologous protein kinases, together with **ataxia telangiectasia and Rad3-related protein (ATR)**, that is central to DNA damage signaling and repair. A related protein kinase called **DNA-PK** is also critical.

ATP-powered pump
Any transmembrane protein that has ATPase activity and couples hydrolysis of ATP to the active transport of an ion or small molecule across a biomembrane against its electrochemical gradient; often simply called *pump*. (Figure 11-9)

ATP synthase
Multimeric protein complex, bound to inner mitochondrial membranes, thylakoid membranes of chloroplasts, and the bacterial plasma membrane, that catalyzes synthesis of ATP during oxidative phosphorylation and photosynthesis; also called F_0F_1 *complex*. (Figure 12-23a)

Aurora kinases
Serine/threonine kinases that play a crucial role in cell division by controlling chromatid segregation. Aurora B kinase destabilizes faulty microtubule-kinetochore interactions by phosphorylating microtubule-binding components within the kinetochore.

autoimmunity
A state in which a host's immune system can mistake the host's own cells and tissues for pathogens and mount an attack against them, characterized by the presence of antibodies and/or T cells specific for antigens in that same individual.

autophagy

Literally, "eating oneself"; the process by which cytosolic proteins and organelles are delivered to the lysosome, degraded, and recycled. Autophagy involves the formation of a double-membrane vesicle called an *autophagosome* or *autophagic* vesicle. (Figure 14-34)

autoradiography
Technique for visualizing radioactive molecules in a sample (e.g., a tissue section or electrophoretic gel) by exposing a photographic film (emulsion) or two-dimensional electronic detector to the sample. The exposed film is called an *autoradiogram* or *autoradiograph*.

autosome
Any chromosome other than a sex chromosome.

axon
Long process extending from the cell body of a neuron that is capable of conducting an electric impulse (**action potential**), generated at the junction with the cell body, toward its distal, branching end (the axon terminus). (Figure 23-1)

axonal transport
Motor protein–mediated transport of organelles and vesicles along microtubules in axons of nerve cells. *Anterograde* transport occurs from cell body toward axon terminal); *retrograde* transport, from axon terminal toward cell body. (Figures 18-16 and 18-17)

axoneme
Bundle of **microtubules** and associated proteins present in **cilia** and **flagella** and responsible for their structure and movement. (Figure 18-31)

bacteria
Class of prokaryotes that constitutes one of the three distinct evolutionary lineages of modern-day organisms; also called *eubacteria*. Phylogenetically distinct from archaea and eukaryotes. (Figure 1-1)

bacteriophage (phage)
Any virus that infects bacterial cells. Some phages are widely used as **vectors** in **DNA cloning**.

basal
See **basolateral**.

basal body

Structure at the base of a **cilium** or **flagellum** from which microtubules forming the **axoneme** assemble; structurally similar to a **centriole**. (Figure 18-31)

basal lamina (pl. basal laminae)
A thin sheet-like network of **extracellular-matrix** components that underlies most animal epithelia and other organized groups of cells (e.g., muscle), separating them from connective tissue or other cells. (Figures 20-22 and 20-23)

base
Any compound, often containing nitrogen, that can accept a proton (H^+) from an acid. Also, commonly used to denote the **purines** and **pyrimidines** in DNA and RNA.

base pair
Association of two complementary **nucleotides** in a DNA or RNA molecule stabilized by hydrogen bonding between their base components. Adenine pairs with thymine or uracil ($A \cdot T$, $A \cdot U$) and guanine pairs with cytosine ($G \cdot C$).

basic helix-loop-helix (bHLH)
See **helix-loop-helix**.

basolateral
Referring to the base (basal) and side (lateral) of a polarized cell, organ, or other body structure. In the case of epithelial cells, the basolateral surface abuts adjacent cells and the underlying **basal lamina**. (Figure 20-10)

B cell
A lymphocyte that matures in the bone marrow and expresses antigen-specific receptors (membrane-bound **immunoglobulin**). After interacting with antigen, a B cell proliferates and differentiates into **antibody**-secreting *plasma cells*.

B-cell receptor
Complex composed of an antigen-specific membrane-bound immunoglobulin molecule and associated signal-transducing Igα and Igβ chains. (Figure 24-19)

Bcl-2 family
A group of evolutionarily conserved proteins that contain BH domains and that either promote or inhibit apoptosis.

benign
Referring to a tumor containing cells that closely resemble normal cells. Benign tumors stay in the tissue where they originate but can be harmful due to continued growth. See also **malignant**.

beta (β)-adrenergic receptors
Seven spanning G protein–coupled receptors that bind adrenaline and related molecules, leading to activation of adenylyl cyclase.

beta (β) sheet
A flat **secondary structure** in proteins that is created by hydrogen bonding between the backbone atoms in two different polypeptide chains or segments of a single folded chain. (Figure 3-5)

beta (β) turn
A short U-shaped **secondary structure** in proteins. (Figure 3-6)

BH3-only protein
A member of the Bcl-2 family that contains only a BH3 domain and that activates apoptosis.

binding-change mechanism
The mechanism by which the β subunits of the F_1 ATP synthase convert ADP and P_i to ATP.

biomolecular condensate
A specialized subunit of a cell, not bounded by a membrane. Often compared to a liquid droplet, it is chemically and physically distinct from its surroundings and is formed as a consequence of a liquid-liquid phase separation or aggregation of proteins and RNAs.

bi-oriented
Indicates that the kinetochores of **sister chromatids** have attached to microtubules emanating from opposite spindle poles.

blastocyst
Stage of mammalian embryo composed of ≈64 cells that have separated into two cell types — **trophectoderm**, which will form extra-embryonic tissues; and the **inner cell mass**, which gives rise to the embryo proper; stage that implants in the uterine wall and corresponds to the *blastula* of other animal embryos. (Figure 22-2)

blastopore
The first opening that forms during embryogenesis of bilaterally symmetric animals, which later becomes the gut. This opening may become either the mouth or the anus.

bromodomain
A protein domain of ∼120 amino acids that binds acetylated lysine; found in chromosome-associated proteins involved in transcriptional activation.

buffer

A solution of the acid (HA) and base (A^-) form of a compound that undergoes little change in pH when small quantities of strong acid or base are added at pH values near the compound's pK_a.

Burkitt's lymphoma
A cancer of B cells caused either by infection with the Epstein-Barr virus or by a chromosomal translocation that causes constitutive activation of the *myc* oncogene.

C_4 pathway
The phosphoenolpyruvate carboxylase-mediated, two-step pathway of CO_2 fixation in mesophyll and bundle sheath cells in plants.

cadherins
A family of dimeric **cell-adhesion molecules** that aggregate in adherens junctions and desmosomes and mediate Ca^{2+}-dependent cell-cell homophilic interactions. (Figure 20-2)

Calvin cycle
See **carbon fixation**.

cancer stem cell
A subpopulation of cancer cells within a tumor that is capable of seeding new tumors.

capsid
The outer proteinaceous coat of a **virus**, formed by multiple copies of one or more protein subunits and enclosing the viral nucleic acid.

CapZ protein
A protein that can bind the (+) end of an actin filament to cap it from actin subunit addition or loss.

CAR T cells
Cytotoxic T cells genetically engineered to contain a chimeric antigen receptor (CAR) that targets an antigen specific to tumor cells.

carbohydrate
General term for certain polyhydroxyaldehydes, polyhydroxyketones, or compounds derived from these usually having the formula $(CH_2O)_n$. Primary type of compound used for storing and supplying energy in animal cells. (Figure 2-18)

carbon fixation
The major metabolic pathway that fixes CO_2 into carbohydrates during photosynthesis; also called the *Calvin cycle*. It is indirectly dependent on light but can occur both in the dark

and light. (Figure 12-40)

carboxy-terminal domain (CTD)
A domain in RNA polymerase II at the carboxyl end of its RPB1 subunit. The domain is made of seven amino acids repeated multiple times, with a consensus sequence of Tyr-Ser-Pro-Thr-Ser-Pro-Ser. (Figure 8-8, red squiggle)

carcinogen
Any chemical or physical agent that can cause cancer when cells or organisms are exposed to it.

carcinoma
A tumor originating from epithelial cells. Carcinomas are the most common type of cancer.

caspases
A class of vertebrate protein-degrading enzymes (proteases) that function in **apoptosis** and work in a cascade with each type activating the next. (Figures 22-36 and 22-42)

catabolism
Cellular degradation of complex molecules to simpler ones usually accompanied by the release of energy. *Anabolism* is the reverse process in which energy is used to synthesize complex molecules from simpler ones.

catalyst
A substance that increases the rate of a chemical reaction without undergoing a permanent change in its structure. Enzymes are proteins with catalytic activity, and ribozymes are RNAs that can function as catalysts. (Figure 3-23)

cation
A positively charged ion.

Cdc14 phosphatase
A dual-specificity protein phosphatase that triggers mitotic CDK inactivation at the end of mitosis.

Cdc25B phosphatase
One of a pair of dual-specificity phosphatases, along with Cdc25C, that de-phosphorylates CDKs on threonine 14 and tyrosine 15, thereby activating CDKs.

Cdc25C phosphatase
One of a pair of dual-specificity phosphatases, along with Cdc25B, that de-phosphorylates CDKs on threonine 14 and tyrosine 15, thereby activating CDKs.

Cdc42 protein
A small signaling GTPase protein that in its active state can bind the nucleation promoting factor WASp as part of the activation of the actin-nucleating Arp2/3 complex.

CDK-activating kinase (CAK)
Phosphorylates CDKs on a threonine residue near the active site. This phosphorylation is essential for CDK activity.

cDNA
DNA molecule copied from an mRNA molecule by reverse transcriptase and therefore lacking the introns present in the DNA of the genome.

cell-adhesion molecules (CAMs)
Proteins in the plasma membrane of cells that bind similar proteins on other cells, thereby mediating cell-cell adhesion. Four major classes of CAMs include the **cadherins, IgCAMs, integrins**, and **selectins**. (Figures 20-1 and 20-2)

cell cycle
Ordered sequence of events in which a eukaryotic cell duplicates its chromosomes and divides into two. The cell cycle normally consists of four phases: G_1 before DNA synthesis occurs; S when DNA replication occurs; G_2 after DNA synthesis; and M when **cell division** occurs, yielding two daughter cells. Under certain conditions, cells exit the cell cycle during G_1 and remain in the G_0 state as nondividing cells. (Figures 1-17 and 19-1)

cell division
See **symmetric cell division**.

cell junctions
Specialized regions on the cell surface through which cells are joined to each other or to the **extracellular matrix**. (Figure 20-11; Table 20-3)

cell line
A population of cultured cells, of plant or animal origin, that has undergone a genetic change allowing the cells to grow indefinitely.

cell lineage
A pathway of cell division and differentiation whereby an ancestral cell gives rise to multiple cell progeny; also refers to the developmental history of a particular cell traced back to the ancestral cell from which it arose.

cell migration
The process whereby cells can move across a substrate.

cell polarity
The ability of cells to organize their internal structure, resulting in changes of cell shape and generating regions of the plasma membrane with different protein and lipid compositions.

cell strain
A population of cultured cells, of plant or animal origin, that has a finite life span and eventually dies, commonly after 25–50 generations.

cell wall
A specialized, rigid **extracellular matrix** that lies next to the plasma membrane, protecting a cell and maintaining its shape; prominent in most fungi, plants, and prokaryotes but absent in most multicellular animals. (Figure 20-43)

cell-matrix adhesion receptor
A cell-surface receptor that binds one or more components of the **extracellular matrix** (ECM), often serving as a link between the ECM and intracellular signaling pathways and the cytoskeleton.

cell-surface receptor
Protein embedded in the plasma membrane that has an extracellular domain that binds an extracellular molecule(s), called a *ligand*. Many cell-surface receptors bind to extracellular signaling molecules; such binding induces conformational changes in the receptor, altering the activity of the receptor's intracellular domain, which transmits the signal to the interior of the cell.

cellular communication
The transfer of information via signaling molecules or ions from one cell to another.

cellular respiration
See **respiration**.

cellulose
A structural polysaccharide made of glucose units linked together by $\beta(1\rightarrow4)$ **glycosidic bonds**. It forms long microfibrils, which are the major component of the **cell wall** in plants.

centriole
Either of two cylindrical structures within the **centrosome** of animal cells and containing nine sets of triplet microtubules; structurally similar to a **basal body**. (Figure 18-6)

centromere

DNA sequence required for proper **segregation** of chromosomes during mitosis and meiosis; the region of mitotic chromosomes where the **kinetochore** forms and that appears constricted. (Figure 6-40)

centrosome (cell center)
Structure located near the nucleus of animal cells that is the primary **microtubule-organizing center (MTOC)**; it contains a pair of **centrioles** embedded in a protein matrix and duplicates before mitosis, with each centrosome becoming a spindle pole. (Figures 18-6 and 18-35a)

centrosome (spindle pole body)
An organelle that serves as the main microtubule organizing center for animal cells. Centrosomes are made from arrangements of two barrel-shaped clusters of microtubules, called **centrioles**, and a complex of proteins that help additional microtubules to form.

centrosome disjunction
During mitotic spindle formation, at the G_2/M transition the protein linker connecting the two original centrioles is dissolved and two separate centrosomes are created.

channels
Membrane proteins that transport water, ions, or small hydrophilic molecules across membranes down their concentration or electric potential gradients.

chaperone
Collective term for two types of proteins — *molecular chaperones* and *chaperonins* — that prevent misfolding of a target protein or actively facilitate proper folding of an incompletely folded target protein, respectively. (Figures 3-19 and 3-20)

checkpoint pathway
Surveillance mechanism that prevents initiation of each step in cell division until earlier steps on which it depends have been completed and mistakes that occurred during the process have been corrected.

chemical equilibrium
The state of a chemical reaction in which the concentration of all products and reactants is constant because the rates of the forward and reverse reactions are equal.

chemical potential energy
The energy stored in the bonds connecting atoms in molecules.

chemiosmosis

Process whereby an electrochemical proton gradient (pH plus electric potential) across a membrane is used to drive an energy-requiring process such as ATP synthesis; also called *chemiosmotic coupling*. See **proton-motive force**. (Figure 12-2)

chemokine
Any of numerous small, secreted proteins that function as chemotatic cues for leukocytes.

chemotaxis
Movement of a cell or organism toward or away from certain chemicals.

chlorophylls
A group of light-absorbing porphyrin pigments that are critical in **photosynthesis**. (Figure 12-35)

chloroplast
A specialized organelle in plant cells that is surrounded by a double membrane and contains internal chlorophyll-containing membranes (**thylakoids**) where the light-absorbing reactions of photosynthesis occur. (Figure 12-33)

cholesterol
A lipid containing the four-ring steroid structure with a hydroxyl group on one ring; a component of many eukaryotic membranes and the precursor of steroid hormones, bile acids, and vitamin D. (Figure 10-8c)

chromatid
One copy of a replicated chromosome, formed during the S phase of the cell cycle, that is joined to the other copy; also called **sister chromatid**. During mitosis, the two chromatids separate, each becoming a chromosome of one of the two daughter cells. (Figure 7-31)

chromatin
Complex of DNA, histones, and nonhistone proteins from which eukaryotic chromosomes are formed. Condensation of chromatin during mitosis yields the visible **metaphase** chromosomes. (Figure 7-22)

chromatin immunoprecipitation
A technique that localizes where a protein of interest associates with the genome.

chromatin-mediated repression
A condensed chromatin structure that sterically blocks transcription factors from interacting with the DNA.

chromosome

In eukaryotes, the structural unit of the genetic material consisting of a single, linear double-stranded DNA molecule and associated proteins. In most prokaryotes, a single, circular double-stranded DNA molecule constitutes the bulk of the genetic material. See also **chromatin** and **karyotype**.

cilium (pl. cilia)
Short, membrane-enclosed structure extending from the surface of eukaryotic cells and containing a core bundle of **microtubules**. Cilia usually occur in groups and beat rhythmically to move a cell (e.g., single-celled organism) or to move small particles or fluid along a surface (e.g., trachea cells). See also **axoneme** and **flagellum**.

circadian clock (circadian oscillator)
A group of proteins and mRNAs whose levels change in a regular pattern that is synchronized with the 24-hour solar clock; allows cells and organisms to anticipate the daily light/dark cycle.

cis (lateral) interactions
Binding interactions between molecules on the plasma membrane in one cell.

cisterna (pl. cisternae)
Flattened membrane-bounded compartment, as found in the Golgi complex and endoplasmic reticulum.

cisternal maturation
The process by which most proteins traverse the Golgi by sequential maturation of cisternal compartments.

citric acid cycle
A set of nine coupled reactions occurring in the matrix of the **mitochondrion** in which acetyl groups are oxidized, generating CO_2, and reduced intermediates used to produce ATP; also called *Krebs cycle* and *tricarboxylic acid (TCA) cycle.* (Figure 12-13)

classical cadherin
A classical cadherin is a member of the calcium-dependent cadherin family of cell-adhesion molecules (CAMs), also called *cell-cell adhesion receptors*, that bind directly to molecules expressed on an adjacent cell. Classical cadherins contain a short C-terminal cytosolic domain, a single transmembrane domain, and five extracellular cadherin domains that mediate cis and trans homophilic binding.

clathrin

A fibrous protein that with the aid of assembly proteins polymerizes into a lattice-like network at specific regions on the cytosolic side of a membrane, thereby forming a clathrin-coated pit that buds off to form a vesicle. (Figure 14-19; Table 14-1)

clone
(1) A population of genetically identical cells, viruses, or organisms descended from a common ancestor. (2) Multiple identical copies of a gene or DNA fragment generated and maintained via **DNA cloning**.

clustered protocadherin
A clustered protocadherin is a member of a subfamily of the cadherins that mediate cell-cell binding and play a role in establishing the complex wiring diagram of neurons in mammalian brains.

co-activator
A protein or protein complex required for transcription activation that does not bind directly to DNA. In contrast, an activator has a DNA-binding domain and binds directly to a DNA transcription control sequence.

codon
Sequence of three nucleotides in DNA or mRNA that specifies a particular amino acid during protein synthesis; also called *triplet*. Of the 64 possible codons, three are stop codons, which do not specify amino acids and cause termination of synthesis. (Table 5-1)

cofilin
An actin regulatory factor that can bind to and disassemble older regions of actin filaments.

cohesin
Protein complex that holds the replicated sister chromatids together.

collagen
A triple-helical glycoprotein rich in glycine and praline that is a major component of the **extracellular matrix** and connective tissues. The numerous subtypes differ in their tissue distribution and the extracellular components and cell-surface proteins with which they associate. (Figure 20-25; Table 20-4)

complement
A group of constitutive serum proteins that bind directly to microbial or fungal surfaces, thereby activating a proteolytic cascade that culminates in formation of the cytolytic *membrane attack complex*. (Figure 24-5)

complementary
(1) Referring to two nucleic acid sequences or strands that can form perfect **base pairs** with each other. (2) Describing regions on two interacting molecules (e.g., an enzyme and its substrate) that fit together in a lock-and-key fashion.

complementary DNA (cDNA)
See **cDNA**.

concentration gradient
In cell biology, a difference in the concentration of a substance in different regions of a cell or embryo or on different sides of a cellular membrane.

condensin
Protein complex that promotes chromosome condensation.

conformation
The precise shape of a protein or other macromolecule in three dimensions resulting from the spatial location of the atoms in the molecule. (Figure 3-13)

connective tissue
Tissue that contains mostly **extracellular matrix** with relatively sparsely distributed cells (i.e., the tissue underlying epithelial cells and their associated basal lamina).

connexins
A family of transmembrane proteins that form **gap junctions** in vertebrates. (Figure 20-22)

conservation
A DNA sequence is considered to be conserved if it has remained substantially unchanged in organisms that are evolutionarily so far apart that most sequences have lost recognizable similarity due to random mutations (the sequence is constrained to perform some important function and so mutational variations have been systematically weeded out by natural selection).

constitutive
Referring to the continuous production or activity of a cellular molecule or the continuous operation of a cellular process (e.g., constitutive secretion) that is not regulated by internal or external signals.

constitutive secretion
The process in which in all cell types at least some proteins are secreted continuously.

contractile bundles

Bundles of **actin** and **myosin** in nonmuscle cells that function in cell adhesion (e.g., *stress fibers*) or cell movement (e.g., *contractile ring* in dividing cells).

co-oriented
Indicates that sister kinetochores attach to microtubules emanating from the *same* spindle pole rather than from opposite spindle poles.

COPI
A class of proteins that coat transport vesicles in the **secretory pathway**. COPI-coated vesicles move proteins from the Golgi to the endoplasmic reticulum and from later to earlier Golgi cisternae. (Table 14-1)

COPII
A class of proteins that coat transport vesicles in the **secretory pathway**. COPII-coated vesicles move proteins from the endoplasmic reticulum to the Golgi. (Table 14-1)

co-repressor
A protein or protein complex required for transcription repression that does not bind directly to DNA. In contrast, a repressor has a DNA-binding domain and binds directly to a DNA transcription control sequence.

cotranslational translocation
Simultaneous transport of a secretory protein into the endoplasmic reticulum as the nascent protein is still bound to the ribosome and being elongated. (Figure 13-6)

cotransport
Protein-mediated movement of an ion or small molecule across a membrane against a concentration gradient driven by coupling to movement of a second molecule down its concentration gradient in the same (**symport**) or opposite (**antiport**) direction. (Figure 11-3 and Table 11-1)

cotransporter
An integral membrane protein that transports two molecules across a membrane. The transport of one molecule along its electrochemical gradient powers the transport of the other against its electrochemical gradient.

covalent bond
Stable chemical force that holds the atoms in molecules together by sharing of one or more pairs of electrons. See also **noncovalent interaction**. (Figures 2-2 and 2-6)

CpG islands

Regions in vertebrate DNA ~100 to ~1000 bp that have an unusually high occurrence of the sequence CG. Many CpG islands function as promoters for transcription initiation, usually in both directions.

CRISPR
Named for *c*lustered *r*egularly *i*nterspaced *s*hort *p*alindromic *r*epeats, a mechanism used by many bacterial cells to protect against invasion by foreign DNA. The mechanism has been utilized in the lab to edit the genomic DNA of metazoan organisms.

cristae
Sheet-like and tubelike invaginations that extend from the boundary membrane into the center of the mitochondrion.

critical cell size
The cell size at which cells can enter the cell cycle. The critical cell size varies with nutrient availability.

critical concentration (C_c)
The concentration of actin monomers above which actin filaments can be formed and below which they disassemble.

cross-exon recognition complex
Large assembly including RNA-binding SR proteins and other components that helps delineate exons in the **pre-mRNAs** of higher eukaryotes and ensure correct **RNA splicing**. (Figure 9-16)

cryoelectron microscopy
A technique whereby a sample is rapidly frozen in water and then imaged at very low temperature in a transmission electron microscope.

cyclic guanosine monophosphate (cGMP)
A **second messenger** that opens cation channels in rod cells and activates protein kinase G in vascular smooth muscle and other cells. (Figures 15-5 and 15-18)

cytochromes
A group of colored, heme-containing proteins, some of which function as **electron carriers** during cellular respiration and photosynthesis. (Figure 12-17a)

cytokine
Any of numerous small, secreted proteins (e.g., erythropoietin, G-CSF, interferons, interleukins) that bind to cell-surface receptors on blood and immune-system cells to trigger their differentiation or proliferation.

cytokine receptor
Member of major class of cell-surface signaling receptors, including those for erythropoietin, growth hormone, interleukins, and interferons. Ligand binding leads to activation of cytosolic JAK kinases associated with the receptor, thereby initiating intracellular signaling pathways. (Figure 16-21)

cytokinesis
The division of the cytoplasm following **mitosis** to generate two daughter cells, each with a nucleus and cytoplasmic organelles. (Figure 17-34)

cytoplasm
Viscous contents of a cell that are contained within the plasma membrane but, in eukaryotic cells, outside the nucleus.

cytoskeleton
Network of fibrous elements, consisting primarily of **microtubules, microfilaments**, and **intermediate filaments**, found in the cytoplasm of eukaryotic cells. The cytoskeleton provides organization and structural support for the cell and permits directed movement of organelles, chromosomes, and the cell itself. (Figures 17-1, 17-2, and 18-1)

cytosol
Unstructured aqueous phase of the cytoplasm excluding organelles, membranes, and insoluble cytoskeletal components.

cytosolic face
The face of a cell membrane directed toward the cytosol. (Figure 10-5)

cytosolic stress granules
Aggregates of proteins and RNA in the cell cytosol that are formed when the cells are under certain types of stresses.

dalton
Unit of molecular mass approximately equal to the mass of a hydrogen atom (1.66×10^{-24} g).

denaturation (melting)
Drastic alteration in the **conformation** of a protein or nucleic acid due to disruption of various noncovalent interactions caused by heating or exposure to certain chemicals; usually results in loss of biological function.

dendrite

Process extending from the cell body of a neuron that is relatively short and typically branched and receives signals from **axons** of other neurons. (Figure 23-1)

dendritic cells
Phagocytic professional **antigen-presenting cells** that reside in various tissues and can detect broad patterns of pathogen markers via their **Toll-like receptors**. After internalizing antigen at a site of tissue injury or infection, they migrate to lymph nodes and initiate activation of **T cells**. (Figure 24-7)

deoxyribonucleic acid
See **DNA**.

depolarization
Decrease in the cytosolic-face negative electric potential that normally exists across the plasma membrane of a cell at rest, resulting in a less inside-negative or an inside-positive **membrane potential**.

depolarized state
When the potential across the plasma membrane is less negative than that of the normal resting state of the cell.

desmin
A subunit protein of the intermediate filaments found in smooth and skeletal muscle.

desmosomal cadherin
Specialized cadherins, desmoglein and desmocollin, that mediate cell-cell binding in anchoring junctions called **desmosomes**.

desmosome
An anchoring junction that functions as a snap-like point of contact between cells.

deuterostomes
A group of bilaterally symmetric animals whose anus develops close to the blastopore and has a dorsal nerve cord. This group includes all chordates (fish, amphibians, reptiles, birds, and mammals) and echinoderms (sea stars, sea urchins).

Dicer
A cytoplasmic double-stranded RNA-specific RNase. Part of the RNase III family, the Dicer enzyme cleaves double-stranded RNA and pre-miRNA into **siRNA** and **miRNA**, respectively. (Figure 9-32)

dipole

A positive charge separated in space from an equal but opposite negative charge.

dipole moment
A quantitative measure of the extent of charge separation, or strength, of a dipole, which for a chemical bond is the product of the partial charge on each atom and the distance between the two atoms.

disaccharide
A small carbohydrate (sugar) composed of two monosaccharides covalently joined by a **glycosidic bond**. (Figure 2-19)

dislocation
Transport of a defective secretory protein from the ER lumen to the cytosol, where it can be degraded by the proteasome.

dissociation constant (K_d)
See **equilibrium constant**.

disulfide bond (—S—S—)
A common covalent linkage between the sulfur atoms on two cysteine residues in different polypeptides or in different parts of the same polypeptide.

diversity
The entire set of antigen-specific receptors encoded by an immune system.

DNA (deoxyribonucleic acid)
Long linear polymer, composed of four kinds of deoxyribose **nucleotides**, that is the carrier of genetic information. See also **double helix**. (Figure 5-3)

DNA-binding domain
The domain of a transcription factor that binds specific, closely related DNA sequences.

DNA cloning
Recombinant DNA technique in which specific cDNAs or fragments of genomic DNA are inserted into a cloning **vector**, which then is incorporated into cultured host cells and maintained during growth of the host cells; also called *gene cloning*. (Figure 6-14)

DNA library
Collection of cloned DNA molecules consisting of fragments of the entire genome (*genomic library*) or of DNA copies of all the mRNAs produced by a cell type (*cDNA library*) inserted into a suitable cloning **vector**.

DNA microarray
An ordered set of thousands of different nucleotide sequences arrayed on a microscope slide or other solid surface; can be used to determine patterns of gene expression in different cell types or in a particular cell type at different developmental stages or under different conditions. (Figures 5-11 and 5-12)

DNA-PK (DNA-dependent protein kinase)
A protein kinase critical for DNA damage signaling and repair, along with the pair of homologous protein kinases **ATM** and **ATR**.

DNA polymerase
An enzyme that copies one strand of DNA (the template strand) to make the complementary strand, forming a new double-stranded DNA molecule. All DNA polymerases add deoxyribonucleotides one at a time in the $5' \rightarrow 3'$ direction to the $3'$ end of a short preexisting primer strand of DNA or RNA.

DNA transposon
A mobile element that transposes directly as DNA (also referred to as just a *transposon*). See also **retrotransposon**. (Figure 7-8)

DNase I footprinting
A technique that reveals the region of a DNA sequence where a transcription factor binds. Samples of a DNA fragment that has been labeled with a radioactive molecule at one end of one strand are digested under carefully controlled conditions in the presence and absence of a DNA-binding protein. Then the DNA is purified away from all of the protein, denatured and electrophoresed, and the resulting gel is subjected to autoradiography. The region protected by the bound protein appears as a gap, or footprint, in the array of bands resulting from digestion in the absence of the protein.

dolichol phosphate
An isoprenoid-based lipid in the ER membrane onto which the precursor for *N*-linked oligosaccharide modification is assembled.

domain
A region of protein that has a distinct, and often independent, function or structure, or that has a distinct topology relative to the rest of the protein.

dominant
In genetics, referring to that allele of a gene expressed in the **phenotype** of a heterozygote; the nonexpressed allele is **recessive**; also refers to the phenotype associated with a

dominant allele. Mutations that produce dominant alleles generally result in a gain of function. (Figure 6-2)

double helix
The most common three-dimensional structure for cellular DNA in which the two polynucleotide strands are antiparallel and wound around each other with complementary bases hydrogen-bonded. (Figure 5-3)

downstream
(1) For a gene, the direction RNA polymerase moves during transcription, which is toward the end of the template DNA strand with a 5′-hydroxyl group. Nucleotides downstream from the +1 position (the first transcribed a nucleotide) are designated +2, +3, and so on. (2) Events that occur later in a cascade of steps (e.g., signaling pathway). See also **upstream**.

Drosha
This nuclear RNase specific for double-stranded RNA acts in concert with a nuclear double-stranded RNA-binding protein called *DGCR8* in humans and cleaves the hairpin region out of the long precursor RNA, generating a pre-miRNA.

duty ratio
The total cycle time of a motor can be divided into time spent in strong states (tending to remain attached, able to exert and support force), and time spent in weak states (tending to detach); the ratio of the two is the duty ratio.

dynamin
A GTPase that can drive the final step of pinching off of a clathrin-coated vesicle from a donor membrane.

dyneins
A class of **motor proteins** that use the energy released by ATP hydrolysis to move toward the (−) end of **microtubules**. Dyneins can transport vesicles and organelles, are responsible for the movement of cilia and flagella, and play a role in chromosome movement during mitosis. (Figures 18-24 and 18-25)

effector
Ultimate component of a signal transduction pathway that elicits a response to the transmitted signal.

effector protein
An enzyme, transcription factor, or cytoskeletal protein whose activation leads directly to changes in cellular activities. (Figure 15-1)

EF hand
A type of helix-loop-helix **structural motif** that occurs in many Ca^{2+}-binding proteins such as **calmodulin**. (Figure 3-7b)

efferent neurons
Nerves that transmit signals from the central nervous system to peripheral tissues such as muscles and endocrine cells.

elastin
A protein that forms the rubberlike amorphous core of elastic fibers.

electric potential
The energy associated with the separation of positive and negative charges. An electric potential is maintained across the plasma membrane of nearly all cells.

electrochemical gradient
The driving force that determines the energetically favorable direction of transport of an ion (or charged molecule) across a membrane. It represents the combined influence of the ion's **concentration gradient** across the membrane and the **membrane potential**.

electron-transport chain
Set of four large multiprotein complexes in the inner mitochondrial membrane plus diffusible cytochrome *c* and coenzyme Q through which electrons flow from reduced electron donors (e.g., NADH) to O_2. Each member of the chain contains one or more bound electron carriers. (Figure 12-19)

electrophoresis
Any of several techniques for separating macromolecules based on their migration in a gel or other medium subjected to a strong electric field. (Figure 3-41)

electrophoretic mobility shift assay (EMSA)
A common affinity electrophoresis technique used to study protein–DNA or protein–RNA interactions.

elongation
Addition of nucleotides to a growing polynucleotide chain, as templated by a complementary DNA coding strand. (Figure 5-24)

elongation factor (EF)
One of a group of nonribosomal proteins required for continued **translation** of mRNA (protein synthesis) following initiation. (Figure 5-37)

embryonic stem (ES) cells
A line of cultured cells derived from very early embryos that can differentiate into a wide range of cell types either in vitro or after reinsertion into a host embryo. (Figure 22-4)

endergonic
Referring to reactions and processes that have a positive *G* and thus require an input of **free energy** in order to proceed; opposite of **exergonic**.

endocytic pathway
Cellular pathway involving **receptor-mediated endocytocis** that internalizes extracellular materials too large to be imported by membrane transport proteins and to remove receptor proteins from the cell surface as a way to down-regulate their activity. (Figure 14-29)

endocytosis
General term for uptake of extracellular material by invagination of the plasma membrane; includes **receptor-mediated endocytosis, phagocytosis**, and pinocytosis.

endoderm
Innermost of the three primary cell layers of the animal embryo; gives rise to the gut and most of the respiratory tract.

endoplasmic reticulum (ER)
Network of interconnected membranous structures within the cytoplasm of eukaryotic cells contiguous with the outer nuclear envelope. The *rough ER,* which is associated with **ribosomes**, functions in the synthesis and processing of secreted and membrane proteins; the *smooth ER*, which lacks ribosomes, functions in lipid synthesis. (Figure 1-13)

endosome
One of two types of membrane-bounded compartments: *early* endosomes (or endocytic vesicles), which bud off from the plasma membrane during receptor-mediated endocytosis, and late endosomes, which have an acidic internal pH and function in sorting of proteins to **lysosomes**. (Figures 14-2 and 14-29)

endosymbiont/endosymbiont hypothesis
Bacterium that resides inside a eukaryotic cell in a mutually beneficial partnership. According to the endosymbiont hypothesis, both mitochondria and chloroplasts evolved from endosymbionts. (Figure 12-7)

endothelium
The thin layer of cells that lines the interior surface of blood and lymphatic vessels.

endothermic
Referring to reactions and processes that have a positive change in **enthalpy**, ΔH, and thus must absorb heat in order to proceed; opposite of **exothermic**.

energy charge
A measure of the fraction of total adenosine phosphates that have "high-energy" phosphoanhydride bonds, which is equal to $([\mathrm{ATP}] + 0.5\,[\mathrm{ADP}])/([\mathrm{ATP}] + [\mathrm{ADP}] + [\mathrm{AMP}])$.

enhanceosome
Large nucleoprotein complex that assembles from transcription factors (activators and repressors) as they bind cooperatively to their binding sites in an **enhancer** with the assistance of DNA-bending proteins. (Figure 8-29)

enhancer
A regulatory sequence in eukaryotic DNA that may be located at a great distance from the gene it controls or even within the coding sequence. Binding of specific proteins to an enhancer modulates the rate of transcription of the associated gene. (Figure 8-18)

enthalpy (ΔH)
Heat; in a chemical reaction, the enthalpy of the reactants or products is equal to their total bond energies.

entropy (S)
A measure of the degree of disorder or randomness in a system; the higher the entropy, the greater the disorder.

enzyme
A protein that catalyzes a particular chemical reaction involving a specific **substrate** or small number of related substrates.

epigenetic modification
Referring to a process that affects the expression of specific genes and is inherited by daughter cells but does not involve a change in DNA sequence.

epigenetics
The study of inherited changes in the phenotype of a cell that do not result from changes in DNA sequence.

epinephrine
A catecholamine secreted by the adrenal gland and some neurons in response to stress; also called *adrenaline*. It functions as both a hormone and neurotransmitter, mediating

fight-or-flight responses (e.g., increased blood glucose levels and heart rate).

epithelia
Tightly packed, sheet-like layers of cells that act as a regulatable, selectively permeable barrier and permit the generation of chemically and functionally distinct compartments in an organism.

epithelial-to-mesenchymal transition (EMT)
Describes a developmental program during which epithelial cells acquire the characteristics of mesenchymal cells. Cells lose adhesive properties and acquire motility.

epithelium (pl. epithelia)
Sheet-like covering, composed of one or more layers of tightly adhering cells, on external and internal body surfaces. (Figure 20-10)

epitope
The part of an antigen molecule that binds to an antigen-specific receptor on B or T cells or to antibody. Large protein antigens usually possess multiple epitopes that bind to antibodies of different specificity.

equilibrium constant (K_{eq})
Ratio of forward and reverse rate constants for a reaction. For a binding reaction, $\mathrm{A} + \mathrm{B} \rightleftarrows \mathrm{AB}$, the association constant (K_{a}) equals K, and the dissociation constant (K_{d}) equals $1/K$.

ERAD (ER-associated protein degradation)
The process by which defective proteins that are unable to fold properly in the ER are degraded. ERAD usually involves dislocation to the cytosol and degradation by the proteasome.

erythropoietin (Epo)
A **cytokine** that triggers production of red blood cells by inducing the proliferation and differentiation of erythroid progenitor cells in the bone marrow. (Figure 16-18b)

ESCRT proteins
A set of proteins responsible for the inward budding of membrane-bounded vesicles into the interior of a multivesicular endosome.

E2F transcription factor (E2F)
A small family of transcription factors related to G_1 CDKs.

E2F transcription factor complex

Transcription factor that promotes the transcription of G_1/S phase cyclins and many other genes whose function is required for S phase.

euchromatin
Less condensed portions of **chromatin** present in interphase chromosomes; includes most transcriptionally active regions. See also **heterochromatin**. (Figure 7-28a)

eukaryotic cells
Cells with a nucleus bounded by a nuclear membrane.

eukaryotic translation initiation factors (eIFs)
Proteins required to initiate protein synthesis in eukaryotic cells. (Figure 5-36)

excision-repair system, DNA
One of several mechanisms for repairing DNA damage due to spontaneous depurination or deamination or exposure to **carcinogens**. These repair systems normally operate with a high degree of fidelity and their loss is associated with increased risk for certain cancers.

excitatory receptor
A membrane receptor that, upon neurotransmitter binding, triggers depolarization and increases the likelihood that the target neuron will fire an action potential.

excitatory synapse
A synapse in which the neurotransmitter induces a depolarization of the postsynaptic cell, favoring generation of an action potential.

exergonic
Referring to reactions and processes that have a negative ΔG and thus release free energy as they proceed; opposite of **endergonic**.

exocytosis
Release of intracellular molecules (e.g., hormones, matrix proteins) contained within a membrane-bounded vesicle by fusion of the vesicle with the plasma membrane of a cell.

exon
Segment of a eukaryotic gene (or of its primary transcript) that reaches the cytoplasm as part of a mature mRNA, rRNA, or tRNA molecule. See also **intron**.

exon shuffling
Evolutionary process for creating new genes (i.e., new combinations of exons) from preexisting ones by recombination between introns of two separate genes or by transposition of mobile DNA elements. (Figures 7-18 and 7-19)

exoplasmic face
The face of a cell membrane directed away from the cytosol. (Figure 10-5)

exosome
Large exonuclease-containing complex that degrades spliced-out introns and improperly processed pre-mRNAs in the nucleus or mRNAs with shortened poly(A) tails in the cytoplasm. (Figure 9-1)

exothermic
Referring to reactions and processes that have a negative change in **enthalpy**, ΔH, and thus release heat as they proceed; opposite of **endothermic**.

extracellular matrix
A complex interdigitating meshwork of proteins and polysaccharides secreted by cells into the spaces between them.

F_0F_1 complex
See **ATP synthase**.

facilitated transport
Protein-aided transport of an ion or small molecule across a cell membrane down its concentration gradient at a rate greater than that obtained by **simple diffusion**; also called *facilitated diffusion*. (Table 11-1)

FAD (flavin adenine dinucleotide)
A small organic molecule that functions as an electron carrier by accepting two electrons from a donor molecule and two H^+ from the solution. (Figure 2-33b)

fatty acid
Any long hydrocarbon chain that has a carboxyl group at one end; a major source of energy during metabolism and a precursor for synthesis of phospholipids, triglycerides, and cholesteryl esters. (Figure 2-21; Table 2-4)

Fc receptor (FcR)
A receptor that recognizes the Fc portion of immunoglobulins.

feedback
A regulatory process in a signaling pathway where one of the later components of the pathway, when activated, inhibits (negative feedback) or activates (positive feedback) an earlier step in the pathway.

feedback repression

An essential feature of most signal transduction pathways, in which an end product of a signaling pathway blocks an early step in that pathway.

fermentation
The conversion of some of the energy in organic molecule nutrients such as glucose into ATP via their oxidation into organic molecule "waste" products such as lactic acid or ethanol, typically involving the simultaneous cyclical reduction and oxidation of $NAD^+/NADH$.

FG-nucleoporins
Proteins on the inner surface of the nuclear pore complex with a globular domain that forms part of the pore structure and a random-coil domain of hydrophilic amino acids punctuated by short repeats rich in phenylalanine and glycine.

fibrillar collagen
These molecules, characterized by long, thin, triple helices composed of Gly-X-Y amino acid triplet repeats, bundle together into microfibrils that associate into higher order fibrils and fibers in the **extracellular matrix** of connective tissues.

fibroblast
A common type of connective tissue cell that secretes **collagen** and other components of the **extracellular matrix**; migrates and proliferates during wound healing and in tissue culture.

fibronectin
An abundant **multi-adhesive matrix protein** that occurs in numerous isoforms, generated by alternative splicing, in various cell types. Binds many other components of the **extracellular matrix** and to integrin adhesion receptors. (Figure 20-34)

filopodia
Slender surface protrusions containing a bundle of actin filaments.

fission (mitochondrial)
The process by which one mitochondrion breaks apart to form two distinct mitochondria.

5′ capping
The initial step in mRNA processing, shortly after RNA polymerase II initiates transcription at the first nucleotide of the first exon of a gene, a protective cap composed of 7-methylguanosine and methylated ribose is added to the 5′ end of eukaryotic mRNAs. (Figure 9-2)

flagellum (pl. flagella)

Long locomotory structure (usually one per cell) extending from the surface of some eukaryotic cells (e.g., **sperm**), whose whiplike bending propels the cell through a fluid medium. Bacterial flagella are smaller and much simpler structures. See also **axoneme** and **cilium**. (Figure 18-31)

flavin adenine dinucleotide
See **FAD**.

flippase
Protein that facilitates the movement of membrane lipids from one leaflet to the other leaflet of a phospholipid bilayer. (Figure 11-15)

fluorescence-activated cell sorter (FACS)
A machine, based on flow cytometry, that separates cells having different levels of fluorescence. (Figure 4-1)

fluorescence in situ hybridization (FISH)
Any of several related techniques for detecting specific DNA or RNA sequences in cells and tissues by treating samples with fluorescent probes that hybridize to the sequence of interest and observing the samples by fluorescence microscopy.

fluorescent staining
General technique for visualizing cellular components by treating cells or tissues with a fluorescent dye–labeled agent (e.g., antibody) that binds specifically to a component of interest and observing the sample by fluorescence microscopy.

focal adhesion/focal contact
Sites of integrin-based cell-matrix adhesion that anchor cells to the **extracellular matrix** and contribute to cellular shape, signaling, force transmission, and movement.

formin
A regulated actin-nucleating protein responsible for generating long, unbranched actin filaments.

Förster resonance energy transfer (FRET)
A technique whereby the distance between two fluorescent proteins — fused to separate proteins or within a single protein — can be determined by measuring the efficiency of energy transfer from one fluorescent protein to the other.

free-energy change (ΔG)
The difference in the Gibbs free energy (G) between the products and reactants for a reaction ($G_{products} - G_{reactants}$), where the free energy is a measure of the potential energy

of a system, which is a function of the enthalpy (H) and entropy (S).

functional complementation
The ability of a functional gene introduced into a mutant cell or organism to restore the activity missing in the mutant.

fusion (mitochondrial)
The process in which two distinct mitochondria merge together.

G_1, G_2 phase
See **cell cycle**.

G_1 cyclin-CDKs
Cyclin-CDK complexes that promote entry into the cell cycle.

G_1/S phase cyclin CDKs
Cyclin-CDK complexes that promote entry into the cell cycle together with G_1 CDKs.

gap junction
Protein-lined channel connecting the cytoplasms of adjacent animal cells that allows passage of ions and small molecules between the cells. See also **plasmodesmata**. (Figure 20-22)

gene
Physical and functional unit of heredity, which carries information from one generation to the next. In molecular terms, it is the entire DNA sequence — including **exons, introns**, and **transcription-control regions** — necessary for production of a functional polypeptide or RNA. See also **transcription unit**.

gene control
All of the mechanisms involved in regulating **gene expression**. Most common is regulation of transcription, although mechanisms influencing the processing, stabilization, and translation of mRNAs help control expression of some genes.

gene conversion
A type of DNA recombination in which one DNA sequence is converted to the sequence of a second, homologous DNA sequence in the same cell.

gene family
Set of genes that arose by duplication of a common ancestral gene and subsequent divergence due to small changes in the nucleotide sequence.

gene knockout
Selective inactivation of a specific gene by replacing it with a nonfunctional (disrupted) allele in an otherwise normal organism.

general import pore
The pore in the outer mitochondrial membrane through which proteins pass as they are imported into mitochondria.

genetic code
The set of rules whereby nucleotide triplets (**codons**) in DNA or RNA specify amino acids in proteins. (Table 5-1)

genetic complementation
Restoration of a wild-type function in diploid heterozygous cells generated from haploid cells, each of which carries a mutation in a different gene whose encoded protein is required for the same biochemical pathway. Complementation analysis can determine if recessive mutations in two mutants with the same mutant phenotype are in the same or different genes. (Figure 6-7)

genome
Total genetic information carried by a cell or organism.

genome-wide association study (GWAS)
A statistical method based on linkage disequilibrium of identifying genes for human diseases or other traits that exhibit genetic heterogeneity or may be polygenic.

genomics
Comparative analyses of the complete genomic sequences from different organisms and determination of global patterns of gene expression; used to assess evolutionary relations among species and to predict the number and general types of RNAs produced by an organism.

genotype
Entire genetic constitution of an individual cell or organism, usually with emphasis on the particular alleles at one or more specific loci.

germ line
Cells in a multicellular organism that are set aside early in development to ultimately give rise to the cells that form the sperm and eggs.

glial cells

Supporting cells of nervous tissue that, unlike neurons, do not conduct electrical impulses. Of the four types, *Schwann cells* and *oligodendrocytes* produce **myelin sheaths**, *astrocytes* function in **synapse** formation, and *microglia* make **trophic factors** and serve in immune responses. (Figure 23-18)

glomeruli
In the brain, glomeruli are spherical structures consisting of a mass of presynaptic axonal terminals forming on postsynaptic dendrites. In the kidney, glomeruli are spherical structures consisting of capillary blood vessels through which blood is filtered into urine.

glucagon
A peptide hormone produced in the cells of pancreatic islets that triggers the conversion of glycogen to glucose by the liver; acts with **insulin** to control blood glucose levels.

gluconeogenesis
A biochemical pathway whereby glucose is synthesized from smaller molecules, often lactate, pyruvate, or certain amino acids.

GLUT4 storage vesicle (GSV)
An intracellular vesicle with GLUT4 transporters in its membrane. Upon insulin stimulation, GSVs fuse with the cell membrane, exposing GLUT4s to the extracellular space, from which they can transport glucose into the cytosol.

glycogen
A very long, branched polysaccharide, composed exclusively of glucose units, that is the primary storage carbohydrate in animals; found primarily in liver and muscle cells.

glycolipid
Any lipid to which a short carbohydrate chain is covalently linked; commonly found in the plasma membrane.

glycolysis
Metabolic pathway in which sugars are degraded anaerobically to lactate or pyruvate in the cytosol with the production of ATP. (Figure 12-3)

glycoprotein
Any protein to which one or more oligosaccharide chains are covalently linked. Most secreted proteins and many membrane proteins are glycoproteins.

glycosaminoglycan (GAG)
A long, linear, highly charged polymer of repeating disaccharides in which many residues often are sulfated. GAGs are major components of the **extracellular matrix**, usually as

components of **proteoglycans**. (Figure 20-30)

glycosidic bond
The covalent linkage between two monosaccharide residues formed when a carbon atom in one sugar reacts with a hydroxyl group on a second sugar with the net release of a water molecule (dehydration). (Figure 2-13)

G protein–coupled receptor (GPCR)
Member of a large class of cell-surface signaling receptors, including those for epinephrine, glucagon, and yeast mating factors. All GPCRs contain seven transmembrane α helices. Ligand binding leads to activation of a coupled trimeric G protein, thereby initiating intracellular signaling pathways. (Figures 15-16 and 15-17)

granulocyte colony–stimulating factor (G-CSF)
A cytokine that induces a granulocyte progenitor cell in the bone marrow to divide and differentiate into granulocytes.

group I introns
A type of self-splicing introns present in nuclear rRNA genes of protozoans.

group II introns
A type of self-splicing introns present in protein-coding genes and some rRNA and tRNA genes in mitochondria and chloroplasts of plants and fungi.

growth factor
An extracellular polypeptide molecule that binds to a cell-surface receptor, triggering an intracellular signaling pathway generally leading to cell proliferation.

growth hormone (GH)
A cytokine secreted by the anterior pituitary gland that stimulates proliferation of a variety of cells.

GTPase superfamily
Group of intracellular switch proteins that cycle between an inactive state with bound GDP and an active state with bound GTP. Includes the G_α subunit of trimeric (large) G proteins, monomeric (small) G proteins (e.g., **Ras**, Rab, Ran, and Rac), and certain **elongation factors** used in protein synthesis. (Figure 3-35)

heat-shock gene
A gene that encodes molecular chaperones that refold denatured proteins and other proteins that help the cell deal with the effects of heat shock.

heat-shock proteins (HSPs)
Proteins that perform several processes that protect cells from the consequences of unfolding a large fraction of cellular proteins.

heat-shock response
A cellular response to an elevated temperature or other stress, whereby synthesis of chaperones is induced to protect the cell from accumulation of unfolded or misfolded proteins.

Hedgehog (Hh)
A family of secreted signaling proteins that are important regulators of the development of most tissues and organs in diverse animal species. Mutations in Hh signal transduction components are implicated in human cancer and birth defects. The receptor is the Patched transmembrane protein. (Figures 16-28 and 16-29)

helicase
(1) Any enzyme that moves along a DNA duplex using the energy released by ATP hydrolysis to separate (unwind) the two strands; required for DNA replication. (2) Activity of certain initiation factors that can unwind the secondary structures in mRNA during initiation of translation.

helix-loop-helix
A conserved DNA-binding **structural motif**, consisting of two α helices connected by a short loop, that is found in many dimeric eukaryotic transcription factors. (Figure 8-25d)

helix-turn-helix
A structural motif in which two alpha helices are connected by a short stretch of connecting residues, sometimes also called a *loop*. Helix-turn-helix/helix-loop-helix structural motifs can perform various functions, including binding calcium and binding DNA.

HER family
Group of receptors, belonging to the receptor tyrosine kinase (RTK) class, that bind to members of the epidermal growth factor (EGF) family of signaling molecules in humans. Overexpression of HER2 protein is associated with some breast cancers. (Figure 16-7)

heredity
The transfer of genetically determined characteristics from one generation to the next.

heterochromatin

Regions of **chromatin** that remain highly condensed and transcriptionally inactive during interphase. (Figure 7-28a)

heterophilic binding
The binding of one cell-adhesion molecule (CAM or cell-cell adhesion receptor) to a different class of CAM on an adjacent cell.

heterotrimeric G proteins
A class of GTPase switch proteins, composed of alpha, beta, and gamma polypeptides, that bind to and are activated by certain cell-surface receptors. When activated, heterotrimeric G proteins release GDP and bind GTP.

heterotypic adhesion
The CAM-mediated binding of one type of cell to a different type of adjacent cell.

heterozygous
Referring to a diploid cell or organism having two different **alleles** of a particular gene.

hexose
A six-carbon **monosaccharide**.

Hif-1α
A transcription factor in metazoans whose level increases in response to a reduction in oxygen.

Hippo pathway
A signal transduction pathway that controls cell growth in the context of tissues.

Hippocampus
A region of the brain, located in the temporal lobe, that is involved in memory.

histone
One of several small, highly conserved basic proteins, found in the **chromatin** of all eukaryotic cells, that associate with DNA in the **nucleosome**. (Figure 7-20)

histone deacetylation
A process by which the lysine residues within the N-terminal tail protruding from the histone core of the nucleosome are deacetylated (an acetyl group is removed from a molecule) as part of gene regulation.

histone octamer
A symmetrical, roughly globular protein complex at the center of the nucleosome.

Holliday structure
An intermediate in DNA recombination with four DNA strands. (Figure 5-22)

homeodomain
Conserved DNA-binding **structural motif** (a helix-turn-helix) found in many developmentally important transcription factors.

homeostasis
The state of an organism or cell in which its internal state is maintained within certain functional limits.

homolog
A protein that shares a common ancestor, and therefore is similar in sequence and/or structure, with another protein.

homologs
Maternal and paternal copies of each morphologic type of chromosome present in a diploid cell; also called *homologues*.

homologous
See **homologs**.

homologous chromosome
One of the two copies of each morphologic type of chromosome present in a diploid cell; also called **homolog**. Each homolog is derived from a different parent.

homologous recombination
See **recombination**.

homology
Similarity in characteristics (e.g., protein and nucleic acid sequences or the structure of an organ) that reflects a common evolutionary origin. Proteins or genes that exhibit homology are said to be homologous and sometimes are called *homologs*. In contrast, *analogy* is a similarity in structure or function that does not reflect a common evolutionary origin.

homophilic binding
The binding of one cell-adhesion molecule (CAM or cell-cell adhesion receptor) to the same kind of CAM on an adjacent cell.

homotypic adhesion
The CAM-mediated binding of one type of cell to the same type of adjacent cell.

homozygous
Referring to a diploid cell or organism having two identical **alleles** of a particular gene.

hormone
Generally any extracellular substance that induces specific responses in target cells; specifically, those signaling molecules that circulate in the blood and mediate endocrine signaling.

hyaluronan
A large, highly hydrated **glycosaminoglycan (GAG)** that is a major component of the **extracellular matrix**; also called *hyaluronic acid* and *hyaluronate*. It imparts stiffness and resilience as well as a lubricating quality to many types of connective tissue. (Figure 20-30a)

hybridization
Association of two **complementary** nucleic acid strands to form double-stranded molecules, which can contain two DNA strands, two RNA strands, or one DNA and one RNA strand. Used experimentally in various ways to detect specific DNA or RNA sequences.

hybridoma
A **clone** of hybrid cells that are immortal and produce **monoclonal antibody**; formed by fusion of a normal antibody-producing B cell with a myeloma cell. (Figure 4-6)

hydrocarbon
Any compound containing only carbon and hydrogen atoms.

hydrogen bond
A **noncovalent interaction** between an atom (commonly oxygen or nitrogen) carrying a partial negative charge and a hydrogen atom carrying a partial positive charge. Important in stabilizing the conformation of proteins and in formation of **base pairs** between nucleic acid strands. (Figure 2-8)

hydropathy profile
A graphical plot of the relative hydrophobicity of the amino acids along the linear sequence of a protein, often used to identify hydrophobic transmembrane-spanning segments.

hydrophilic
Interacting effectively with water. See also **polar**.

hydrophobic
Not interacting effectively with water; in general, poorly soluble or insoluble in water. See also **nonpolar**.

hydrophobic effect
The tendency of nonpolar molecules or parts of molecules to associate with each other in aqueous solution so as to minimize their direct interactions with water; commonly called a *hydrophobic interaction* or *bond*. (Figure 2-11)

hyperpolarization
Increase in the magnitude of the cytosolic-face negative electric potential that normally exists across the plasma membrane of a cell at rest, resulting in a more negative **membrane potential**.

immune checkpoint pathways
Genetically engineered cytotoxic T cells that contain a chimeric antigen receptor (CAR) targeting a tumor-specific antigen.

immunoediting
The process in which tumor cells are initially eliminated by the immune system, reach a steady state plateau, and then eventually escape from immune control by a variety of molecular mechanisms.

immunity
A state of protection against pathogens and their products (toxins), afforded by the presence of immune cells (B cells, T cells) and their products (immunoglobulins, cytokines).

immunoblotting
Technique in which proteins separated by electrophoresis are attached to a nitrocellulose or other membrane, and specific proteins then are detected by use of labeled antibodies; also called *Western blotting*.

immunoglobulin
Any of the serum proteins, produced by fully differentiated **B cells**, that can function as antibodies; also occur in membrane-bound form as part of the **B-cell receptor**. Immunoglobulins are divided into five main classes (*isotypes*) that exhibit distinct functional properties. See also **antibody**. (Figures 24-9 and 24-10)

immunoglobulin fold
Evolutionarily ancient structural motif found in antibodies, the T-cell receptor, and numerous other eukaryotic proteins not directly involved in antigen-specific recognition; also called *Ig domain*. (Figure 24-13b)

immunoprecipitation (IP)

A technique that uses antibodies to separate a target molecule of interest from other molecules in a complex mixture in solution by cross-linking the target molecule into a large aggregate, resulting in the formation of an insoluble solid (precipitate) that can be easily separated and analyzed.

in situ hybridization
Any technique for detecting specific DNA or RNA sequences in cells and tissues by treating samples with single-stranded RNA or DNA probes that hybridize to the sequence of interest. (Figure 6-30)

induced pluripotent stem (iPS) cells
A mammalian cell with properties of an embryonic stem cell that is formed from a differentiated cell type by expression of one or more transcription factors or other genes that confer pluripotency.

inflammasome
A multisubunit protein complex involved in the production of pro-inflammatory cytokines in response to a noxious substance, which may either be bacterially derived or is composed of a (foreign) material such as asbestos or uric acid crystals.

inflammation
Localized response to injury or infection that leads to the activation of immune-system cells and their recruitment to the affected site; marked by the four classical signs of redness, swelling, heat, and pain. (Figure 24-7)

inhibitory receptor
A membrane receptor that, upon neurotransmitter binding, triggers hyperpolarization and decreases the likelihood that the target neuron will fire an action potential.

inhibitory synapse
A synapse in which the neurotransmitter induces a hyperpolarization of the postsynaptic cell, inhibiting generation of an action potential.

initiation
The process by which an RNA polymerase separates DNA strands and synthesizes the first phosphodiester bond of an RNA chain as templated by the DNA strand that enters the RNA polymerase active site. (Figure 5-24)

initiation factor (IF)
One of a group of nonribosomal proteins that promote the proper association of ribosomes and mRNA and are required for initiation of **translation** (protein synthesis). (Figure 5-36)

initiator
A DNA sequence that specifies transcription initiation within the sequence.

inner cell mass (ICM)
The part of an early embryo that will form the embryo proper but not the extra-embryonic tissues, including the placenta.

inner mitochondrial membrane
The highly invaginated membrane that lies immediately underneath the outer mitochondrial membrane and that comprises the boundary membrane, cristae, and crista junctions.

inside-out signaling
Transfer of information from the extracellular environment (e.g., via hormones, growth factors, and **extracellular matrix**) to inside the cell, usually mediated via transmembrane receptors and adapter proteins.

insulin
A protein hormone produced in the β cells of the pancreatic islets that stimulates uptake of glucose into muscle and fat cells; acts with **glucagon** to help regulate blood glucose levels. Insulin also functions as a growth factor for many cells.

integral membrane protein
Any protein that contains one or more hydrophobic segments embedded within the core of the **phospholipids bilayer**; also called *transmembrane protein*. (Figure 13-10)

integrins
A large family of heterodimeric transmembrane proteins that function as adhesion receptors, promoting cell-matrix adhesion, or as cell-adhesion molecules, promoting cell-cell adhesion. (Table 20-4)

interleukins
Large group of cytokines, some released in response to inflammation, that promote proliferation and functioning of T cells and antibody-producing B cells of the immune system.

intermediate filament
Cytoskeletal fiber (10 nm in diameter) formed by polymerization of related, but tissue-specific, subunit proteins, including **keratins, lamins**, and **neurofilaments**. (Figure 18-49; Table 18-2)

intermembrane space

The mitochondrial compartment between the inner and outer mitochondrial membranes, which is continuous with the spaces inside the cristae.

interneurons
Nerves that receive signals from other nerve cells and that in turn transmit signals to other nerve cells.

interspersed repeats
Sequences from transposons that occur at multiple sites throughout the genomes of multicellular animals and plants. (Figure 7-8; Table 7-1)

intrinsically disordered region (IDR)
A segment (region) of a protein that is very flexible, with no fixed, well-ordered conformation. If the entire protein has no fixed conformation, it is called an *intrinsically disordered protein (IDP)*.

intron
Part of a primary transcript (or the DNA encoding it) that is removed by splicing during RNA processing and is not included in the mature, functional mRNA, rRNA, or tRNA.

ionic bond (ionic interaction)
A **noncovalent interaction** between a positively charged ion (cation) and negatively charged ion (anion).

iron-response element–binding protein (IRE-BP)
4Fe-4S cluster-containing proteins that act as cellular iron sensors. When the cytosolic $Fe2^{+}$ concentration is too low, the iron in the Fe-S clusters dissociates from the protein and the IRE-BP becomes an active RNA-binding protein that binds to a specific nucleotide sequence within stem-loop secondary structures in the untranslated regions of the ferritin and transferrin receptor mRNAs. (Figure 9-35).

isoelectric point (pI)
The pH of a solution at which a dissolved protein or other potentially charged molecule has a net charge of zero and therefore does not move in an electric field. (Figure 3-42)

isoform
One of several forms of the same protein whose amino acid sequences differ slightly and whose general activities are similar. Isoforms may be encoded by different genes or by a single gene whose primary transcript undergoes **alternative splicing**.

isotype
The term for a class of immunoglobulins, based on their distinct biochemical properties.

karyotype
Number, sizes, and shapes of the entire set of **metaphase** chromosomes of a eukaryotic cell. (Chapter 7 opening figure)

keratins
A group of **intermediate filament** proteins found in epithelial cells that assemble into heteropolymeric filaments. (Figure 18-51)

kinase
An enzyme that transfers the terminal (γ) phosphate group from ATP to a substrate. Protein kinases, which phosphorylate specific serine, threonine, or tyrosine residues, play a critical role in regulating the activity of many cellular proteins. See also **phosphatases**. (Figure 3-34)

kinesins
A class of **motor proteins** that use energy released by ATP hydrolysis to move toward the (+) end of a **microtubule**. Kinesins can transport vesicles and organelles and play a role in chromosome movement during mitosis. (Figures 18-18 through 18-20)

kinetic energy
Energy of movement, such as the motion of molecules.

kinetochore
A multilayer protein structure located at or near the **centromere** of each mitotic chromosome from which microtubules extend toward the spindle poles of the cell; plays an active role in movement of chromosomes toward the poles during anaphase. (Figure 18-42)

lagging strand
One of the two daughter DNA strands formed at a **replication fork** as short, discontinuous segments (Okazaki fragments), which are synthesized in the $5' \rightarrow 3'$ direction and later joined. See also **leading strand**. (Figure 5-11)

lamellipodium
A two-dimensional network of actin filaments under the plasma membrane found at the leading edge of a motile cell.

laminin
Large heterotrimeric **multi-adhesive matrix protein** that is found in all **basal lamina**. (Figure 20-24)

lamins

A group of **intermediate filament** proteins that form a fibrous network, the **nuclear lamina**, on the inner surface of the nuclear envelope.

late endosome
See **endosome**.

lateral
See **basolateral**.

leading edge
The actin-rich region at the front of a migrating cell.

leading strand
One of the two daughter DNA strands formed at a **replication fork** by continuous synthesis in the $5' \rightarrow 3'$ direction. The direction of leading-strand synthesis is the same as movement of the replication fork. See also **lagging strand**. (Figure 5-11)

lectin
Any protein that binds tightly to specific sugars. Lectins assist in the proper folding of some glycoproteins in the endoplasmic reticulum and can be used in affinity chromatography to purify glycoproteins or as reagents to detect them in situ.

leucine zipper
A type of coiled-coil **structural motif** composed of two α helices that form specific homo- or heterodimers; common motif in many eukaryotic transcription factors. (Figures 3-7 and 8-25c)

leukemia
Cancer originating from one of the cell lineages responsible for the formation of red or white blood cells.

ligand
Any molecule, other than an enzyme **substrate**, that binds tightly and specifically to a macromolecule, usually a protein, forming a macromolecule-ligand complex.

light-harvesting complexes (LHCs)
Specialized proteins that use pigments such as chlorophylls to efficiently capture light energy and transmit it to reaction centers to generate high-energy electrons.

linkage
In genetics, the tendency of two different loci on the same chromosome to be inherited together. The closer two loci are, the lower the frequency of **recombination** between them

and the greater their linkage.

linker DNA
A "beads-on-a-string" organization of nucleosomes separated by a variable length (–50–150 bp) of DNA.

lipid-anchored membrane protein
Any protein that is tethered to a cellular membrane by one or more covalently attached lipid groups, which are embedded in the phospholipids bilayer. (Figure 9-19)

lipid raft
Microdomain in the plasma membrane that is enriched in cholesterol, sphingomyelin, and certain proteins.

liposome
Artificial spherical **phospholipid bilayer** structure with an aqueous interior that forms in vitro from phospholipids and may contain membrane proteins. (Figure 10-3c)

liquid chromatography
An analytical technique used to separate components in a liquid, usually by flowing the liquid across a surface whose properties result in the components of the liquid differentially interacting with the surface.

long interspersed elements (LINEs)
Abundant mobile elements in mammals generated by retrotransposons lacking long terminal repeats. (Figure 7-17)

long noncoding RNA (lncRNA)
RNAs that can be many kilobases in length and lack long open reading frames.

long terminal repeats (LTRs)
Direct repeat sequences, containing up to 600 base pairs, that flank the coding region of integrated retroviral DNA and viral **retrotransposons**.

loss of heterozygosity (LOH)
The process by which the heterozygous, wild-type copy of a gene is lost to uncover a loss-of-function mutation. This is particularly important in the expression of tumor-suppressor mutations.

low-density lipoprotein (LDL)
A class of lipoprotein, containing apolipoprotein B-100, that is a primary transporter of cholesterol in the form of cholesteryl esters between tissues, especially to the liver. (Figure

14-27)

lumen
The aqueous interior of an organelle.

lymphocytes
Two classes of white blood cells that can recognize foreign molecules (**antigens**) and mediate immune responses. B lymphocytes (B cells) are responsible for production of antibodies; T lymphocytes (T cells) are responsible for destroying virus and bacteria-infected cells, foreign cells, and cancer cells.

lymphomas
Tumors that originate in lymphocytes.

lysosome
Small organelle that has an internal pH of 4–5, contains hydrolytic enzymes, and functions in degradation of materials internalized by endocytosis and of cellular components in autophagy. (Figures 1-13 and 4-12)

M (mitotic) phase
See **cell cycle**.

macromolecule
A molecule containing a very large number of atoms; the three main types of biological macromolecules are proteins, nucleic acids, and polysaccharides.

macrophages
Phagocytic leukocytes that can detect broad patterns of pathogen markers via **Toll-like receptors**. They function as professional **antigen-presenting cells** and are a major source of **cytokines**.

major histocompatibility complex (MHC)
Set of adjacent genes that encode class I and class II MHC molecules and other proteins required for antigen presentation, as well as some complement proteins; called the *H-2 complex* in mice and the *HLA complex* in humans. (Figure 24-22)

malignant
Referring to a tumor or tumor cells that can invade surrounding normal tissue and/or undergo **metastasis**. See also **benign**.

mannose 6-phosphate (M6P)

A specific modification of *N*-linked oligosaccharides responsible for sorting of proteins in the trans-Golgi to the lysosome.

MAP kinase
Any of a family of protein kinases that are activated in response to cell stimulation by many different growth factors and that mediate cellular responses by phosphorylating specific transcription factors and other target proteins. (Figure 16-14)

matriglycan
A polymer of the Xyl-GlcUA disaccharide that is attached to proteins such as dystroglycan via a phosphorylated *O*-linked mannose attached to the protein and intervening short phosphorylated oligosaccharide. Matriglycan provides a binding site for ECM molecules, such as laminin and perlecan.

matrix
The lumen of the innermost compartment of the mitochondrion; also the fibrous proteins and carbohydrates external to a cell (called the ***extracellular matrix***).

matrix metalloproteases (MMPs)
Proteolytic enzymes that employ the metal zinc in their active sites. They operate in the extracellular space, where they cut proteins in the **extracellular matrix** and sometimes other proteins (e.g., some cell-surface receptors).

mechanoreceptors
A sensory cell that responds to a mechanical stress or movement; also the intracellular molecule that senses this stress or movement.

mechanosensor
(1) Any of several types of sensory structures that are embedded in various tissues and respond to touch, the positions and movements of the limbs and head, pain, and temperature. (2) An individual molecule or complex that responds to a mechanical stimulus by changing its shape and activity.

Mediator
A very large multiprotein complex that forms a molecular bridge between transcriptional activators bound to an **enhancer** and to RNA polymerase II bound at a **promoter**; functions as a coactivator in stimulating transcription. (Figures 8-36 and 8-37)

meiosis
In eukaryotes, a special type of cell division that occurs during maturation of germ cells; comprises two successive nuclear and cellular divisions with only one round of DNA

replication. Results in production of four genetically nonequivalent haploid cells (gametes) from an initial diploid cell. (Figure 6-3)

membrane contact sites (MCSs)
Sites at which membranes from two organelles bind to one another via their protein constituents.

membrane potential
Electric potential difference, expressed in volts, across a membrane due to the slight excess of positive ions (cations) on one side and negative ions (anions) on the other. (Figures 11-18 and 11-19)

membrane transport protein
Collective term for any integral membrane protein that mediates movement of one or more specific ions or small molecules across a cellular membrane regardless of the transport mechanism. (Figure 11-2)

memory
The ability of an antigen-experienced immune system to respond more rapidly to a re-exposure to that same antigenic stimulus.

meristem
Organized group of undifferentiated, dividing cells that are maintained at the tips of growing shoots and roots in plants. All the adult structures arise from meristems.

merotelic attachment
Indicates that a single kinetochore attaches to microtubules emanating from two opposite spindle poles.

messenger RNA
See **mRNA**.

metaphase
Stage of mitosis at which condensed chromosomes are aligned equidistant between the poles of the mitotic spindle but have not yet started to segregate toward the spindle poles. (Figures 18-38 and 18-39)

metastasis
Spread of cancer cells from their site of origin and establishment of areas of secondary growth.

micelle

A water-soluble spherical aggregate of phospholipids or other amphipathic molecules that form spontaneously in aqueous solution.

Michaelis constant (Km)
A parameter that describes the affinity of an enzyme for its substrate and equals the substrate concentration that yields the half-maximal reaction rate. A similar parameter describes the affinity of a transport protein for the transported molecule or the affinity of a receptor for its ligand. (Figure 3-25)

microexons
The most common and extensively conserved type of alternatively spliced exons in the central nervous system. They are unusually short: 3 to 27 bases long in multiples of three so that they maintain the reading frames of up- and downstream exons of more typical longer lengths (average ~150 bases in humans).

microfilament
Cytoskeletal fiber (≈7 nm in diameter) that is formed by polymerization of monomeric globular (G) actin; also called actin filament. Microfilaments play an important role in muscle contraction, cytokinesis, cell movement, and other cellular functions and structures. (Figure 17-4)

micro-RNA
See **miRNA**.

microsatellites
Simple-sequence repeated DNA sequences 1–13 bases long (most are <5 bp) that occur in the human genome in tandem repeats of 150 repeats or fewer.

microsome
The cellular fraction that contains ribosomes bound to the ER membrane. This fraction corresponds to the rough ER as characterized by electron microscopy.

microtubule
Cytoskeletal fiber (≈25 nm in diameter) that is formed by polymerization of **α, β-tubulin** monomers and exhibits structural and functional polarity. Microtubules are important components of cilia, flagella, the mitotic spindle, and other cellular structures. (Figures 18-2 and 18-3)

microtubule-associated protein (MAP)
Any protein that binds to microtubules and regulates their stability. (Figures 18-13 through 18-15)

microtubule-organizing center
See **MTOC**.

microvilli
Small, membrane-covered projections on the surface of an animal cell, containing cores of actin filaments. Numerous microvilli are present on the absorptive surface of intestinal epithelial cells, increasing the surface area for transport of nutrients. (Figures 17-4 and 20-10)

miRNA (micro-RNA)
Any of numerous small, endogenous cellular RNAs, 20–30 nucleotides long, that are processed from double-stranded regions of hairpin secondary structures in long precursor RNAs. A single strand of the mature miRNA associates with several proteins to form an **RNA-induced silencing complex (RISC)** that inhibits translation of a target mRNA to which the miRNA hybridizes imperfectly. Several miRNAs must hybridize to a single mRNA to inhibit its translation. See also **siRNA**. (9-32)

mitochondria-associated membranes (MAMs)
Portions of the endoplasmic reticulum that closely contact regions of mitochondria, influencing mitochondrial shape, function, and fission.

mitochondrial DNA
DNA present in the mitochondrial matrix that encodes a limited number of mitochondrial genes.

mitochondrial inner membrane
A single continuous membrane comprising the boundary membrane, mitochondrial cristae, and crista junctions that separates the intermembrane space and the mitochondrial matrix. The mitochondrial electron-transport chain and the ATP synthase reside in this membrane. Protons in the matrix are pumped across the inner membrane to generate a proton-motive force.

mitochondrial intermembrane space
The fluid-filled space between the mitochondrial outer and inner membranes.

mitochondrial matrix
The fluid-filled space surrounded by the mitochondrial inner membrane. Protons in the matrix are pumped across the inner membrane to generate a proton-motive force.

mitochondrial outer membrane

The continuous membrane surrounding mitochondria that permits transfer of molecules from the cytosol into the mitochondria and mediates direct contact with other organelles via membrane contact sites.

mitochondrion (pl. mitochondria)
Large organelle that is surrounded by two phospholipid bilayer membranes, contains DNA, and carries out **oxidative phosphorylation**, thereby producing most of the ATP in eukaryotic cells. (Figures 1-21 and 12-6)

mitogen
Any extracellular molecule, such as a growth factor, that promotes cell proliferation.

mitophagy
The process by which mitochondria are surrounded by a membrane and then delivered to lysosomes for degradation.

mitosis
In eukaryotic cells, the process whereby the nucleus divides, producing two genetically equivalent daughter nuclei with the diploid number of chromosomes. See also **cytokinesis** and **meiosis**. (Figure 18-36)

mitotic cyclin-CDKs
Cyclin-CDK complexes that promote entry into and progression through mitosis.

mitotic spindle
A specialized temporary structure, present in eukaryotic cells during mitosis, that captures the chromosomes and then pushes and pulls them to opposite sides of the dividing cell; also called *mitotic apparatus*. (Figures 18-38 and 18-39)

molecular complementarity
Lock-and-key kind of fit between the shapes, charges, hydrophobicity, and/or other physical properties of two molecules or portions thereof that allow formation of multiple **noncovalent interactions** between them at close range. (Figure 2-12)

monoclonal antibody
Antibody produced by the progeny of a single B cell and thus a homogeneous protein that recognizes a single antigen (epitope). It can be produced experimentally by use of a **hybridoma**. (Figure 4-6)

monomer
Any small molecule that can be linked chemically with others of the same type to form a **polymer**. Examples include amino acids, nucleotides, and monosaccharides.

monomeric G protein
A monomeric GTPase with a structure similar to that of the Ras protein that changes conformation when a bound GTP is hydrolyzed to GDP and phosphate. (Figure 15-7)

monopolin complex
Protein complex that promotes the co-orientation of **sister chromatids** during meiosis I in budding yeast.

monosaccharide
Any simple sugar with the formula $(CH_2O)_n$ where $n = 3–7$.

monotelic attachment
Indicates that only one of the sister kinetochore pair attached to microtubules.

morphogen
A signaling molecule whose concentration determines the fate of target-differentiating cells.

motor neurons
Nerve cells that form synapses on muscle cells.

motor protein
Any member of a special class of mechanochemical enzymes that use energy from ATP hydrolysis to generate either linear or rotary motion; also called *molecular motor*. See also **dyneins**, **kinesins**, and **myosins**.

mRNA (messenger RNA)
Any RNA that specifies the order of amino acids in a protein (i.e., the primary structure). It is produced by **transcription** of DNA by RNA polymerase. In eukaryotes, the initial RNA product (primary transcript) undergoes processing to yield functional mRNA. See also **translation**. (Figure 5-27)

mRNA surveillance
The processes that lead to the degradation of a pre-mRNA or mRNA that has been improperly processed.

mRNP exporter
A heterodimeric protein that binds to mRNA-containing ribonucleoprotein particles (mRNPs) and directs their export from the nucleus to cytoplasm by interacting transiently with **nucleoporins** in the nuclear pore complex. (Figure 9-27)

MTOC (microtubule-organizing center)

General term for any structure (e.g., centrosome, spindle pole, basal body) that organizes microtubules in cells. (Figure 18-5)

mTOR protein kinase
The protein kinase that is the signaling component of the mTORC1 complex.

mTORC1
A large complex of proteins formed on the cytosolic surface of a lysosome that integrates signals from the level of amino acids, ATP, and extracellular hormones and that regulates many aspects of cell growth and division via the mTOR protein kinase.

multi-adhesive matrix proteins
Group of long flexible proteins that bind to other components of the **extracellular matrix** and to cell-surface receptors, thereby cross-linking matrix components to the cell membrane. Examples include **laminin**, a major component of the basal lamina, and **fibronectin**, present in many tissues.

multi-hit model
The fundamental concept that most cancers progress slowly by cells sequentially acquiring multiple mutations activating different oncogenic processes.

multimeric
For proteins, containing several polypeptide chains (or subunits).

multipass membrane protein
A membrane protein with more than one transmembrane-spanning domain.

multipotent
Describes a stem cell that is able to give rise to several, but not all, types of differentiated cells in an organism.

multiprotein complexes
An assembly of multiple, distinct proteins that performs a distinct function, such as mediating one or more steps in the electron-transport pathway in mitochondria.

multiubiquitinylation
The covalent addition of several single ubiquitin molecules, each at a distinct site, on a single target protein.

multivesicular endosomes
Endosomes that segregate membrane proteins destined for degradation in the lysosome on vesicles that bud into the interior of the endosome.

MuSK
A receptor tyrosine kinase localized in the myotube plasma membrane that both induces clustering of acetylcholine receptors and serves to attract the termini of growing motor neuron axons.

mutagen
A chemical or physical agent that induces mutations.

mutation
In genetics, a permanent, heritable change in the nucleotide sequence of a chromosome, usually in a single gene; commonly causes an alteration in the function of the gene product.

myelin sheath
Stacked specialized cell membrane that forms an insulating layer around vertebrate **axons** and increases the speed of impulse conduction. (Figure 23-19)

myofibril
Long, slender structures within cytoplasm of muscle cells consisting of a regular repeating array of **sarcomeres** composed of thick (**myosin**) filaments and thin (**actin**) filaments. (Figure 17-29)

myosin light-chain kinase
(Ch. 17) A protein kinase that can phosphorylate a specific light chain of myosin-II to activate it.

myosins
A class of **motor proteins** that have actin-stimulated ATPase activity. Myosins move along actin **microfilaments** during muscle contraction and cytokinesis and also mediate vesicle translocation. (Figure 17-22)

NAD^+ (nicotinamide adenine dinucleotide)
A small organic molecule that functions as an electron carrier by accepting two electrons from a donor molecule and one H^+ from the solution. (Figure 2-33a)

$NADP^+$ (nicotinamide adenine dinucleotide phosphate)
Phosphorylated form of NAD1 that is used extensively as an electron carrier in biosynthetic pathways and during photosynthesis.

Na^+/K^+ ATPase
A P-class ATP-powered pump that couples hydrolysis of one ATP molecule to export of Na^+ ions and import of K^+ ions; largely responsible for maintaining the normal intracellular

concentrations of Na^+ (low) and K^+ (high) in animal cells; commonly called Na^+/K^+ *pump*. (Figure 11-12)

natural killer (NK) cells
Components of the innate immune system that nonspecifically detect and kill virus-infected cells and tumor cells. (Figure 24-6)

necroptosis
A type of necrosis triggered by extracellular hormones that causes inflammation.

necrosis
Cell death resulting from tissue damage or other pathology; usually marked by swelling and bursting of cells with release of their contents. Contrast with **apoptosis**.

neoblasts
Stem cells in planaria that can proliferate and regenerate many or all body cells.

neurofilaments (NFs)
A group of **intermediate filament** proteins, found only in neurons, that contribute to axonal structure and rate of transmission of action potentials down axons. (Figure 18-2b)

nervous system
Consists of the central (brain and spinal cord) and peripheral (nerves outside of the brain and spinal cord) nervous systems, and regulates all aspects of bodily function.

neuromuscular junction (NMJ)
The chemical synapse formed between a presynaptic motor neuron and a postsynaptic muscle cell.

neuron (nerve cell)
Any of the impulse-conducting cells of the nervous system. A typical neuron contains a cell body; multiple short, branched processes (**dendrites**); and one long process (**axon**). (Figure 23-1)

neurotransmitter
Extracellular signaling molecule that is released by the presynaptic neuron at a chemical **synapse** and relays the signal to the postsynaptic cell. The response elicited by a neurotransmitter, either excitatory or inhibitory, is determined by its receptor on the postsynaptic cell. (Figures 23-26 and 23-27)

neurotrophins

Family of structurally and functionally related **trophic factors** that bind to receptors called *Trks* and are required for survival of neurons; include nerve growth factor (NGF) and brain-derived neurotrophic factor (BDNF).

neutrophils
Phagocytic leukocytes that are attracted to sites of tissue damage and migrate into the tissue. Once activated, neutrophils secrete various chemokines, cytokines, bacteria-destroying enzymes (e.g., lysozyme), and other products that contribute to **inflammation** and help clear invading pathogens.

NF-κB
A transcription factor that is sequestered in the cytosol until its inhibitory protein is degraded.

nicotinamide adenine dinucleotide
See $\mathbf{NAD^+}$.

nicotinamide adenine dinucleotide phosphate
See $\mathbf{NADP^+}$.

***N*-linked oligosaccharide**
A branched oligosaccharide chain attached to the side-chain amino group of an asparagine residue in a glycoprotein. See also ***O*-linked oligosaccharide**.

nociceptor
Mechanosensor that responds to pain associated with injury to body tissues caused by mechanical trauma, heat, electricity, or toxic chemicals.

node of Ranvier (node)
An unmyelinated area of axonal membrane about 1 μm in length, which separates each region of myelin formed by an individual glial cell from the next region.

noncovalent interaction
Any relatively weak chemical interaction that does not involve an intimate sharing of electrons. (Figures 2-6 and 2-12)

nondisjunction
Mis-segregation of chromosomes during mitosis, resulting in aneuploidy or trisomy.

nonhomologous end joining
A pathway that repairs double-strand breaks in DNA in which the break ends are directly ligated without the need for a homologous template.

nonpolar
Referring to a molecule or structure that lacks any net electric charge or asymmetric distribution of positive and negative charges. Nonpolar molecules generally are less soluble in water than polar molecules and are often water insoluble.

nuclear bodies
Roughly spherical, functionally specialized regions in the nucleus, containing specific proteins and RNAs; many function in the assembly of ribonucleoprotein (RNP) complexes. The most prominent type is the nucleolus.

nuclear envelope
Double-membrane structure surrounding the nucleus; the outer membrane is continuous with the endoplasmic reticulum and the two membranes are perforated by **nuclear pore complexes**. (Figure 1-13a)

nuclear lamina
Fibrous network on the inner surface of the nuclear envelope composed of lamin intermediate filaments. (Figure 19-22b)

nuclear pore complex (NPC)
Large, multiprotein structure, composed largely of nucleoporins, that extends across the nuclear envelope. Ions and small molecules freely diffuse through NPCs; large proteins and ribonucleoprotein particles are selectively transported through NPCs with the aid of soluble proteins. (Figure 13-32a, b)

nuclear receptor
Member of a class of intracellular receptors that bind lipid-soluble molecules (e.g., steroid hormones), forming ligand-receptor complexes that activate transcription; also called *steroid receptor superfamily*. (Figure 8-45d)

nuclear speckles
A type of structure within the cell nucleus enriched in pre-mRNA splicing factors.

nuclear transport receptor
A general class of proteins that facilitate protein transport into or out of the nucleus by binding to a nuclear import sequence or a nuclear export sequence.

nucleation promoting factor (NPF)
A regulatory protein involved in activating the Arp2/3 complex in the nucleation of actin filaments.

nucleic acid

A polymer of **nucleotides** linked by **phosphodiester bonds.** DNA and RNA are the primary nucleic acids in cells.

nucleocapsid
A viral **capsid** plus the enclosed nucleic acid.

nucleoporin
Large group of proteins that make up the **nuclear pore complex**. One class (**FG-nucleoporins**) participates in nuclear import and export.

nucleoside
A small molecule composed of a **purine** or **pyrimidine** base linked to a pentose (either ribose or deoxyribose). (Table 2-3)

nucleosome
Structural unit of **chromatin** consisting of a disk-shaped core of **histone** proteins around which a 147-bp segment of DNA is wrapped. (Figure 7-20)

nucleotide
A **nucleoside** with one or more phosphate groups linked via an ester bond to the sugar moiety, generally to the 5′ carbon atom. DNA and RNA are polymers of nucleotides containing deoxyribose and ribose, respectively. (Figure 2-16; Table 2-3)

nucleus
Large membrane-bounded organelle in eukaryotic cells that contains DNA organized into chromosomes; synthesis and processing of RNA and ribosome assembly occur in the nucleus.

odorants
Small molecules that bind olfactory receptors to activate the sense of smell.

Okazaki fragments
Short (<1000 bases), single-stranded DNA fragments that are formed during synthesis of the **lagging strand** in DNA replication and are rapidly joined by DNA ligase to form a continuous DNA strand. (Figure 5-11)

olfactory receptors
A class of G protein–coupled receptors that bind odorants to activate the sense of smell.

oligodendrocytes
Glial cells in the central nervous system that create myelin sheaths that wrap around and insulate central neuronal axons.

oligopeptide
A small to medium-size linear polymer composed of amino acids connected by peptide bonds. The terms *peptide* and *oligopeptide* are often used interchangeably.

***O*-linked oligosaccharide**
Oligosaccharide chain that is attached to the side-chain hydroxyl group in a serine or threonine residue in a glycoprotein. See also ***N*-linked oligosaccharides**.

oncogene
A gene whose product is involved either in transforming cells in culture or in inducing cancer in animals. Generally is a mutant form of a normal gene (**proto-oncogene**) for a protein involved in the control of cell growth or division. (Figure 25-20)

oncogenesis
The genetic process by which cancer forms as a result of many genetic changes to a normal somatic cell.

open reading frame (ORF)
Region of sequenced DNA that is not interrupted by stop codons in one of the triplet reading frames. An ORF that begins with a start codon (usually AUG) and extends for 100 or more codons is called a *long open reading frame* and has a high probability of encoding a protein.

opsonization
The decoration of bacterial or mammalian cells with immunoglobulins and/or fragments of complement proteins to facilitate activation of phagocytic and antigen-presenting cells.

optogenetics
A technique in which channelrhodopsins are expressed in electrically excitable cells, allowing their membrane potential to be manipulated using light.

organelle
Any membrane-limited subcellular structure found in eukaryotic cells. (Figures 1-13, 1-18, 1-20, and 1-21)

osmosis
Net movement of water across a semipermeable membrane (permeable to water but not to solute) from a solution of lesser to one of greater solute concentration. (Figure 11-7)

outer mitochondrial membrane
The smooth outside boundary of the mitochondrion.

outside-in signaling
Transfer of information from inside the cell to outside the cell, usually mediated via transmembrane receptors and adapter proteins.

oxidation
Loss of electrons from an atom or molecule as occurs when a hydrogen atom is removed from a molecule or oxygen is added; opposite of **reduction**.

oxidation potential
The voltage change when an atom or molecule loses an electron; a measure of the tendency of a molecule to lose an electron. For a given oxidation reaction, the oxidation potential has the same magnitude but opposite sign as the **reduction potential** for the reverse (reduction) reaction.

oxidative phosphorylation
The phosphorylation of ADP to form ATP driven by the transfer of electrons to oxygen (O_2) in bacteria and mitochondria. Involves generation of a **proton-motive force** during electron transport and its subsequent use to power ATP synthesis.

p53
The product of a **tumor-suppressor gene** that plays a critical role in the arrest of cells with damaged DNA. Inactivating mutations in the *p53* gene are found in many human cancers. (Figure 25-15)

paracellular pathway
The extracellular pathway between cells by which molecules and ions move from one side of an epithelium to the other without crossing the plasma membranes of the cells.

paracrine
Referring to signaling mechanism in which a target cell responds to a signaling molecule (e.g., growth factor, neurotransmitter) that is produced by a nearby cell(s) and reaches the target by diffusion.

paratope
The portion of an immunoglobulin molecule that contacts the antigen for which it is specific.

patch clamping
Technique for determining ion flow through a single ion channel or across the membrane of an entire cell by use of a micropipette whose tip is applied to a small patch of the cell membrane. (Figure 11-22)

patterning genes
Genes involved in metazoan development that determine the general organization of the animal, including the major body axes and segmentation.

P body
Dense cytoplasmic domain, containing no ribosomes or translation factors, that functions in repression of translation and degradation of associated mRNAs; also called *cytoplasmic RNA-processing body*.

P-class pump
A pump that possess two identical catalytic α subunits, each of which contains an ATP-binding site. Most also have two smaller α subunits, which usually have regulatory functions. During transport, at least one of the α subunits becomes phosphorylated (hence the name "P" class), and the transported ions move through the phosphorylated subunit.

PDZ domain
A protein domain ~80–90 amino acids long that usually binds to a specific, short, C-terminal sequence motif in a "target" protein.

pentose
A five-carbon **monosaccharide**. The pentoses ribose and deoxyribose are present in RNA and DNA, respectively. (Figure 2-16)

peptide
A small linear polymer composed of amino acids connected by peptide bonds. The terms *peptide* and *oligopeptide* are often used interchangeably. See also **polypeptide**.

peptide bond
The covalent amide linkage between amino acids formed between the amino group of one amino acid and the carboxyl group of another with the net release of a water molecule (dehydration). (Figure 2-13)

peptidoglycan
A polysaccharide chain cross-linked by peptide cross-bridges in a bacterial cell wall that confers rigidity and helps to determine the cell's shape.

pericentriolar material
Amorphous material seen by thin-section electron microscopy surrounding the centrioles of animal cells. Pericentriolar material contains many components, including the gamma-tubulin ring complex (gamma-TuRC), which promotes nucleation of microtubule assembly. (Figure 18-6)

peripheral membrane protein
Any protein that associates with the cytosolic or exoplasmic face of a membrane but does not enter the hydrophobic core of the phospholipid bilayer. See also **integral membrane protein**. (Figure 10-1)

perlecan
A large multidomain **proteoglycan** component of the **extracellular matrix** (ECM) that binds to many ECM components, cell-surface molecules, and growth factors; a major component of the **basal lamina**.

peroxisome
Small organelle that contains enzymes for degrading fatty acids and amino acids by reactions that generate hydrogen peroxide, which is converted to water and oxygen by catalase.

pervasive transcription
The phenomenon where the vast majority of the genome is transcribed, well beyond the boundaries of known genes.

pH
A measure of the acidity or alkalinity of a solution defined as the negative logarithm of the hydrogen ion concentration in moles per liter: $pH = -\log [H^+]$. Neutrality is equivalent to a pH of 7; values below this are acidic and those above are alkaline.

phagocyte
Any cell that can ingest and destroy pathogens and other particulate antigens. The primary phagocytes are neutrophils, macrophages, and dendritic cells.

phagocytosis
Process by which relatively large particles (e.g., bacterial cells) are internalized by certain eukaryotic cells in a process that involves extensive remodeling of the actin cytoskeleton; distinct from **receptor-mediated endocytosis**. (Figure 17-19)

phenotype
The detectable physical and physiological characteristics of a cell or organism determined by its **genotype**; also, the specific trait associated with a particular **allele**.

Philadelphia chromosome
A translocation between chromosome 9 and chromosome 22 causing constitutive activation of ABL kinase and giving rise to chronic myeloid leukemia.

phosphatase

An enzyme that removes a phosphate group from a substrate by hydrolysis. Phosphoprotein phosphatases act with protein kinases to control the activity of many cellular proteins. (Figure 3-36)

phosphoanhydride bond
A type of high-energy bond formed between two phosphate groups, such as the γ and β phosphates and the β and α phosphates in ATP. (Figure 2-31)

phosphodiester bond
Chemical linkage between adjacent nucleotides in DNA and RNA; consists of two phosphoester bonds, one on the 5′ side of the phosphate and another on the 3′ side. (Figure 5-2)

phosphoglycerides
Amphipathic derivatives of glycerol 3-phosphate that generally consist of two hydrophobic fatty acyl chains esterified to the hydroxyl groups in glycerol and a polar head group attached to the phosphate; the most abundant lipids in biomembranes. (Figures 2-20 and 9-8a)

phosphoinositides
A group of membrane-bound lipids containing phosphorylated inositol derivatives; some function as **second messengers** in several signal transduction pathways. (Figures 15-27 and 16-16)

phospholipase
One of several enzymes that cleave various bonds in the hydrophilic end of **phospholipids**. (Figure 10-12)

phospholipid
The major class of lipids present in biomembranes, including **phosphoglycerides** and **sphingolipids**. (Figures 2-20 and 10-8a, b)

phospholipid bilayer
A two-layer, sheet-like structure in which the polar head groups of phospholipids are exposed to the aqueous media on either side and the nonpolar fatty acyl chains are in the center; the foundation for all biomembranes. (Figure 10-3a, b)

phosphorylation
The covalent addition of a phosphate group to a molecule such as a sugar or a protein. The hydrolysis of ATP often accompanies phosphorylation, providing energy to drive the

reaction and the phosphate group that is covalently added to the target molecule. Enzymes that catalyze phosphorylation are called *kinases*.

photoelectron transport
Light-driven electron transport that generates a charge separation across the **thylakoid membrane** that drives subsequent events in photosynthesis. (Figure 12-31)

photorespiration
A reaction pathway that competes with CO_2 fixation (**Calvin cycle**) by consuming ATP and generating CO_2, thus reducing the efficiency of photosynthesis. (Figure 12-42)

photosynthesis
Complex series of reactions occurring in some bacteria and in plant **chloroplasts** in which light energy is used to generate carbohydrates from CO_2, usually with the consumption of H_2O and evolution of O_2.

photosystems
Multiprotein complexes, present in all photosynthetic organisms, that consist of light-harvesting complexes containing **chlorophylls** and a reaction center where **photoelectron transport** occurs. (Figure 12-37)

photosystem I (PSI)
One of two multiprotein complex photosystems that converts light energy to high-energy electrons, which in turn drive the formation of NADPH. Primarily in unstacked regions of the thylakoid membranes.

photosystem II (PSII)
One of two multiprotein complex photosystems that converts light energy to high-energy electrons, which in turn drive the formation of NADPH. Primarily in stacked regions of the thylakoid membranes.

phragmoplast
In plants, a temporary structure, formed during telophase, whose membranes become the plasma membranes of the daughter cells and whose contents develop into the new cell wall between them. (Figure 18-48)

plakins
A family of proteins that help attach **intermediate filaments** to other structures.

planar cell polarity (PCP)
A signaling pathway that organizes the orientation of individual cells in a cell layer.

plaque assay
Technique for determining the number of infectious viral particles in a sample by culturing a diluted sample on a layer of susceptible host cells and then counting the clear areas of lysed cells (plaques) that develop.

plasma membrane
The membrane surrounding a cell that separates the cell from its external environment; consists of a **phospholipid bilayer** and associated membrane lipids and proteins. (Figures 1-13a, 10-1, and 10-5)

plasmid
Small, circular extrachromosomal DNA molecule capable of autonomous replication in a cell; commonly used as a **vector** in **DNA cloning**.

plasmodesmata (sing. plasmodesma)
Tubelike cell junctions that interconnect the cytoplasms of adjacent plant cells and are functionally analogous to **gap junctions** in animal cells. (Figure 20-43)

pluripotent
Describes a type of stem cell that can differentiate into a wide range of cell types from the three primary germ layers, but not necessarily cells that form the placenta.

point mutation
Change of a single nucleotide in DNA, especially in a region coding for protein; can result in formation of a codon specifying a different amino acid or a stop codon. Addition or deletion of a single nucleotide will cause a shift in the **reading frame**.

polar
Referring to a molecule or structure with a net electric charge or asymmetric distribution of positive and negative charges. Polar molecules are usually soluble in water.

polarity
In cell biology, the presence of functional and/or structural differences in distinct regions of a cell or cellular component. See also **cell polarity**.

poly(A) tail
A long chain of adenine nucleotides that is added to an mRNA molecule during RNA processing to increase the stability of the molecule.

polyclonal antibody
Antibodies raised in an experimental animal by injecting a specific protein.

polymer
Any large molecule composed of multiple identical or similar units (**monomers**) linked by covalent bonds. (Figure 2-13)

polymerase chain reaction (PCR)
Cycles of synthesis of a specific segment of DNA carried out in vitro. The reaction is carried out by sequential cycles of heating to dissociate DNA strands, annealing to specific oligonucleotide primers, and DNA synthesis with a heat-stable DNA polymerase. Each reaction cycle leads to a doubling in the amount of the target DNA.

polypeptide
Linear polymer of amino acids connected by peptide bonds, usually containing 20 or more residues. See also **protein**.

polyribosome
A complex containing several **ribosomes**, all translating a single messenger RNA; also called *polysome*. (Figure 5-39)

polysaccharide
Linear or branched polymer of **monosaccharides** linked by glycosidic bonds and usually containing more than 15 residues. Those with fewer than 15 residues are often called *oligosaccharides*.

polytene chromosome
Enlarged chromosome composed of many parallel copies of itself formed by multiple cycles of DNA replication without chromosomal separation; found in the salivary glands and some other tissues of *Drosophila* and other dipteran insects. (Figure 7-36)

polyubiquitination
The covalent addition of a chain of covalently linked ubiquitin molecules to a site on a target protein.

polyunsaturated
Referring to a compound (e.g., fatty acid) in which two or more of the carbon-carbon bonds are double or triple bonds.

porins
Class of trimeric transmembrane proteins through which small water-soluble molecules can cross the membrane; present in outer mitochondrial and chloroplast membranes and in the outer membrane of gram-negative bacteria. (Figure 10-18)

post-translational modification (PTM)

The covalent and generally enzymatic modification of proteins following protein biosynthesis.

post-translational translocation
Some secretory proteins enter the ER lumen after translation has been completed.

potential energy
Stored energy. In biological systems, the primary forms of potential energy are chemical bonds, concentration gradients, and electric potentials across cellular membranes.

precursor mRNA (pre-mRNA)
The primary RNA product formed by transcription of a gene. Splicing of introns and modifications to the 5′ and 3′ ends of the pre-mRNA are necessary to form a mature mRNA that can be transported out of the nucleus and translated on ribosomes. (Figures 5-27 and 9-2)

pre-rRNA
Large precursor ribosomal RNA that is synthesized in the nucleolus of eukaryotic cells and processed to yield three of the four RNAs present in ribosomes. (Figures 9-43 and 9-44)

primary cilium
The single nonmotile cilium present on almost all vertebrate cells that serves as a sensory organelle to detect extracellular signals.

primary structure
In proteins, the linear arrangement (sequence) of amino acids within a polypeptide chain.

primase
A specialized RNA polymerase that synthesizes short stretches of RNA used as primers for DNA synthesis. (Figure 5-12)

primer
A short nucleic acid sequence containing a free 3′-hydroxyl group that forms **base pairs** with a complementary template strand and functions as the starting point for addition of nucleotides to copy the template strand.

progenitor (precursor) cells
A type of undifferentiated cell that, when provided with the appropriate signals, will divide and differentiate into one or a few cell types.

programmed cell death
See **apoptosis**.

prokaryotic organisms
Class of organisms, including the **bacteria** (eubacteria) and archaea, that lack a true membrane-limited nucleus and other organelles. (Figure 1-1)

prolactin
A cytokine released during pregnancy of mammals that induces the development of mammary glands to produce and secrete milk proteins.

prometaphase
Second stage in mitosis, during which the nuclear envelope and nuclear lamina break down and microtubules assembled from the spindle poles "capture" chromosome pairs at specialized structures called **kinetochores**. (Figures 18-38 and 18-39)

promoter
DNA sequence that determines the site of **transcription** initiation for an RNA polymerase. (Figure 5-24)

promoter-proximal element
Any regulatory sequence in eukaryotic DNA that is located within ~200 base pairs of the transcription start site. Transcription of many genes is controlled by multiple promoter-proximal elements. (Figure 8-18)

prophase
Earliest stage in mitosis, during which the chromosomes condense, the duplicated centrosomes separate to become the spindle poles, and the mitotic spindle begins to form. (Figures 18-38 and 18-39)

protease
Any enzyme that cleaves one or more peptide bonds in target proteins.

proteasome
Large multifunctional protease complex in the cytosol that degrades intracellular proteins marked for destruction by attachment of multiple **ubiquitin** molecules. (Figure 3-32)

protein
A macromolecule composed of one or more linear **polypeptide** chains and folded into a characteristic three-dimensional shape (**conformation**) in its native, biologically active state.

protein disulfide isomerase (PDI)
An enzyme, present in all eukaryotic cells, and especially abundant in the ER of secretory cells in organs such as the liver and pancreas, where large quantities of proteins that

contain disulfide bonds are produced. (Figure 13-19)

protein domain
Distinct regions of a protein's three-dimensional structure. A *functional* domain exhibits a particular activity characteristic of the protein; a *structural* domain is ≈40 or more amino acids in length, arranged in a distinct secondary or tertiary structure; a *topological* domain has a distinctive spatial relationship to the rest of the protein.

protein family
Set of homologous proteins encoded by a **gene family**.

protein kinase (PK)
An enzyme that chemically adds a phosphate group, usually the gamma phosphate from ATP, to a serine, threonine, or tyrosine residue of another protein.

protein kinase B (PKB)
Cytosolic enzyme that is recruited to the plasma membrane by signal-induced **phosphoinositides** and subsequently activated; also called **Akt**. (Figure 16-17)

protein phosphatase
An enzyme that chemically removes a phosphate group from another protein by hydrolysis.

proteoglycans
A group of glycoproteins (e.g., perlecan and aggrecan) that contain a core protein to which is attached one or more **glycosaminoglycan (GAG)** chains. They are found in nearly all animal extracellular matrices, and some are integral membrane proteins. (Figure 20-33)

proteome
All the proteins in a cellular compartment, intact cell, organ, or organism.

proteomics
The systematic study of the amounts, modifications, interactions, localization, and functions of all or subsets of proteins at the whole-organism, tissue, cellular, and subcellular levels.

proteostasis
The process of maintaining proteins and their activities at appropriate levels, and for making rapid adjustments in these levels in response to changing conditions.

proton-motive force
The energy equivalent of the proton (H^+) concentration gradient and electric potential gradient across a membrane; used to drive ATP synthesis by **ATP synthase**, transport of

molecules against their concentration gradient, and movement of bacterial flagella. (Figure 12-2)

proton pump
A protein that uses an external source of energy (ATP, high-energy electrons) to transport protons across a membrane against an electrochemical gradient. In mitochondria and chloroplasts, a proton pump can generate the proton-motive force used to synthesize ATP.

proton pumping
The process catalyzed by a proton pump in which an external source of energy (ATP, high-energy electrons) is used to transport protons across a membrane against an electrochemical gradient.

proto-oncogene
A normal cellular gene that encodes a protein usually involved in regulation of cell growth or differentiation and that can be mutated into a cancer-promoting **oncogene**, either by changing the protein-coding segment or by altering its expression.

protostomes
A group of bilaterally symmetric animals whose mouth develops close to the blastopore and has a ventral nerve cord. This group includes worms, insects, and mollusks.

pseudogene
DNA sequence that is similar to that of a functional gene but does not encode a functional product; probably arose by sequence drift of duplicated genes.

pulse-chase
A type of experiment in which a radioactive small molecule is added to a cell for a brief period (the pulse) and then is replaced with an excess of the unlabeled form of the same small molecule (the chase). Used to detect changes in the cellular location of a molecule or its metabolic fate over time. (Figure 3-45)

purines
A class of nitrogenous compounds containing two fused heterocyclic rings. Two purines, adenine (A) and guanine (G), are base components of nucleotides found in DNA and RNA. See also **base pair**. (Figure 2-17)

pyrimidines
A class of nitrogenous compounds containing one heterocyclic ring. Two pyrimidines, cytosine (C) and thymine (T), are base components of nucleotides found in DNA; in RNA, uracil (U) replaces thymine. See also **base pair**. (Figure 2-17)

pyruvate
The ionized form of a three-carbon, carboxylic acid that is a key intermediate in energy metabolism.

Q cycle
An evolutionarily conserved mechanism employed by mitochondrial complex III that uses the net oxidation of one $CoQH_2$ molecule to transfer four protons into the mitochondrial intermembrane space and two electrons to two cytochrome *c*. The cytochrome *bf* complex in the chloroplast also uses a Q cycle.

quaternary structure
The number and relative positions of the polypeptide chains in multimeric (multisubunit) proteins. (Figure 3-10b)

Rab proteins
A family of small GTPases that regulate the tethering and targeting of transport vesicles.

Rac protein
A small GTPase that can induce the formation of actin filaments in a lamellipodium by regulating the activity of the Arp2/3 complex through the WAVE complex.

radioisotope
Unstable form of an atom that emits radiation as it decays. Several radioisotopes are commonly used experimentally as labels in biological molecules. (Table 3-1)

Ran protein
A small GTPase that is responsible for most unidirectional transport of large proteins into and out of the nucleus through the nuclear pore.

Ras protein
A monomeric member of the **GTPase superfamily** of switch proteins that is tethered to the plasma membrane by a lipid anchor and functions in intracellular signaling pathways; activated by ligand binding to receptor tyrosine kinases and some other cell-surface receptors. (Figures 16-10 and 16-12)

rate constant
A constant that relates the concentrations of reactants to the rate of a chemical reaction.

rate-limiting step
The slowest step in a multistep process, for example, in a multistep enzymatic reaction or a multistep biosynthetic pathway.

Rb protein
Inhibitor of the E2F transcription factor family and thus a key regulator of cell cycle entry.

reactive oxygen species (ROS)
Highly chemically reactive, oxygen-containing molecules, both radicals and non-radicals, that can damage many biological molecules and can serve as signaling molecules.

reading frame
The sequence of nucleotide triplets (**codons**) that runs from a specific translation start codon in an mRNA to a stop codon. Some mRNAs can be translated into different polypeptides by reading in two different reading frames. (Figure 4-17)

receptor
Any protein that specifically binds another molecule to mediate cell-cell signaling, adhesion, endocytosis, or other cellular process. Commonly denotes a protein located in the plasma membrane, cytosol, or nucleus that binds a specific extracellular molecule (**ligand**), which often induces a conformational change in the receptor, thereby initiating a cellular response. See also **adhesion receptor** and **nuclear receptor**. (Figure 15-3)

receptor protein
A protein that binds a ligand, which could be a small molecule such as adrenalin, a growth factor such as epidermal growth factor, a hormone such as insulin, or another macromolecule, usually with engagement of a signaling cascade as a consequence.

receptor-mediated endocytosis
Uptake of extracellular materials bound to specific cell-surface receptors by invagination of the plasma membrane to form a small membrane-bounded vesicle (early endosome). (Figure 14-29)

recessive
In genetics, referring to that allele of a gene that is not expressed in the **phenotype** when the **dominant** allele is present; also refers to the phenotype of an individual (homozygote) carrying two recessive alleles. Mutations that produce recessive alleles generally result in a loss of the gene's function. (Figure 6-2)

recombinant DNA
Any DNA molecule formed in vitro by joining DNA fragments from different sources.

recombination
Any process in which chromosomes or DNA molecules are cleaved and the fragments are rejoined to give new combinations. Homologous recombination occurs during meiosis,

giving rise to crossing over of homologous chromosomes. Homologous recombination and nonhomologous recombination (i.e., between chromosomes of different morphologic type) also occur during several DNA-repair mechanisms and can be carried out in vitro with purified DNA and enzymes. (Figure 6-27)

redox reaction
An oxidation-reduction reaction in which one or more electrons are transferred from one reactant to another.

reduction
Gain of electrons by an atom or molecule as occurs when a hydrogen atom is added to a molecule or oxygen is removed. The opposite of **oxidation**.

reduction potential (*E*)
The voltage change when an atom or molecule gains an electron; a measure of the tendency of a molecule to gain an electron. For a given reduction reaction, *E* has the same magnitude but opposite sign as the **oxidation potential** for the reverse (oxidation) reaction.

refractory period
The period of time during which a neuron is hyperpolarized and unable to respond to stimuli because the sodium channels are inactivated.

regulated secretion
Proteins are stored inside the cell in specialized vesicles known as *secretory granules* until a signal for exocytosis causes them to be released.

release factor (RF)
One of two types of nonribosomal proteins that recognize stop codons in mRNA and promote release of the completed polypeptide chain, thereby terminating **translation** (protein synthesis). (Figure 5-38)

replication fork
Y-shaped region in double-stranded DNA at which the two strands are separated and replicated during DNA synthesis; also called *growing fork*. (Figure 5-11)

replication origin
Unique DNA segment present in an organism's genome at which DNA replication begins. Eukaryotic chromosomes contain multiple origins, whereas bacterial chromosomes and plasmids usually contain just one.

repolarization

After the action potential passes through a section of a neuron, channel proteins and pumps restore the inside-negative resting potential.

reporter gene
A gene encoding a protein that is easily assayed (e.g., β-galactosidase, luciferase). Reporter genes are used in various types of experiments to indicate activation of the promoter to which the reporter gene is linked.

repression domain
A region of a repressor transcription factor that will inhibit transcription when fused to a DNA-binding domain.

repressor
Specific **transcription factor** that inhibits transcription.

residue
General term for the repeating units in a polymer that remain after covalent linkage of the monomeric precursors.

resolution
The minimum distance between two objects that can be distinguished by an optical apparatus; also called *resolving power*.

respiration
The conversion of energy in nutrients into ATP via a set of reactions involving a series of protein-catalyzed, membrane-associated oxidation and reduction reactions, called an *electron-transport chain*, that are ultimately coupled to the addition of P_i to ADP (oxidative phosphorylation) to form ATP and transfer of electrons to oxygen or other inorganic electron acceptors.

respiratory chain
See **electron-transport chain**.

respiratory control
Dependence of mitochondrial oxidation of NADH and $FADH_2$ on the supply of ADP and P_i for ATP synthesis.

resting K^+ channels
Nongated K^+ ion channels in the plasma membrane that, in conjunction with the high cytosolic K^+ concentration produced by the **Na^+/K^+ ATPase**, are primarily responsible for generating the inside-negative resting **membrane potential** in animal cells.

resting membrane potential
The electrical potential difference that exists across the membrane of a cell that is in a non-excited state. The electrical potential results from the differential distribution of ions across the membrane.

restriction enzyme
Any enzyme that recognizes and cleaves a specific short sequence, the *restriction site*, in double-stranded DNA molecules; used extensively to produce **recombinant DNA** in vitro; also called *restriction endonuclease*. (Figure 6-11)

restriction point
Point in the mammalian cell cycle after which cells are no longer responsive to proliferation regulatory signals.

retrograde
Backward-moving transport vesicle that retrieves proteins from the cis-Golgi cisterna and returns them to the ER.

retromer
A protein complex that coats vesicles budding from late endosomes, which recycle the M6P receptor back to the trans-Golgi network.

retrotransposon
Type of eukaryotic **transposable DNA element** whose movement in the genome is mediated by an RNA intermediate and involves a reverse-transcription step. See also **DNA transposon**. (Figure 7-8)

retrovirus
Type of eukaryotic virus containing an RNA genome that replicates in cells by first making a DNA copy of the RNA. This viral DNA is inserted into cellular chromosomal DNA, forming a provirus, and gives rise to further genomic RNA as well as the mRNAs for viral proteins. (Figure 5-43)

reverse transcriptase
Enzyme found in retroviruses that catalyzes a complex reaction in which a double-stranded DNA is synthesized from a single-stranded RNA template. (Figure 7-14)

RGD motif
The Arg-Gly-Asp sequence motif that serves as a binding site for integrins.

R group

A portion of a molecule, or a chemical group within a larger molecule, that is covalently bonded as an appendage to the main body or core of the molecule. In an amino acid, the R group is the side chain that is attached to the alpha carbon atom and that confers the distinct characteristics of the amino acid.

Rho protein
A protein that can activate myosin light chain kinase and formins in the assembly of contractile structures such as stress fibers. The protein family of which Cdc42, Rac, and Rho are members has also been collectively named *Rho proteins*.

ribonucleic acid (RNA)
See **RNA**.

ribonucleoprotein (RNP) complex
General term for any complex composed of proteins and RNA. Most RNA molecules are present in the cell in the form of RNPs.

ribosomal RNA (rRNA)
Any one of several large RNA molecules that are structural and functional components of ribosomes. Often designated by their sedimentation coefficient: 28S, 18S, 5.8S, and 5S rRNA in higher eukaryotes. (Figure 5-34)

ribosome
A large complex comprising several different **rRNA** molecules and as many as 83 proteins, organized into a large subunit and small subunit; the engine of **translation** (protein synthesis). (Figures 5-34 and 5-35)

ribozyme
An RNA molecule with catalytic activity. Ribozymes function in RNA splicing and protein synthesis.

RNA (ribonucleic acid)
Linear, single-stranded polymer, composed of ribose **nucleotides**. mRNA, rRNA, and tRNA play different roles in protein synthesis; a variety of small RNAs play roles in controlling the stability and translation of mRNAs and in controlling chromatin structure and transcription. (Figure 5-29)

RNA editing
Unusual type of RNA processing in which the sequence of a pre-mRNA is altered.

RNA-induced silencing complex (RISC)

Large multiprotein complex associated with a short single-stranded RNA (**siRNA** or **miRNA**) that mediates degradation or translational repression of a complementary or near-complementary mRNA.

RNA interference (RNAi)
Functional inactivation of a specific gene by a corresponding double-stranded RNA that induces either inhibition of translation or degradation of the complementary single-stranded mRNA encoded by the gene but not that of mRNAs with a different sequence. (Figure 6-41)

RNA polymerase
An enzyme that copies one strand of DNA (the *template* strand) to make the **complementary** RNA strand using as substrates ribonucleoside triphosphates. (Figure 5-24)

RNA polymerase II
An enzyme that synthesizes precursors of mRNAs and most snRNA and miRNAs.

RNA splicing
A process that results in removal of **introns** and joining of **exons** in pre-mRNAs. See also **spliceosome**. (Figures 9-8 and 9-9)

rough endoplasmic reticulum
The region of the endoplasmic reticulum with ribosomes attached to the cytosolic face; site of synthesis of secreted and many membrane proteins.

rRNA
See **ribosomal RNA**.

rubisco (ribulose 1,5-bisphosphate carboxylase)
Enzyme located in chloroplasts that catalyzes the first reaction in the Calvin cycle, the addition of CO_2 to a five-carbon sugar (ribulose 1,5-bisphosphate) to form two molecules of 3-phosphoglycerate. (Figure 12-40)

S (synthesis) phase
See **cell cycle**.

saltatory conduction
The propagation of action potentials from one node of Ranvier to the next along myelinated axons.

sarcoma

A tumor that originates from bone or other types of connective tissue.

sarcomere
Repeating structural unit of striated (skeletal) muscle composed of organized, overlapping thin (**actin**) filaments and thick (**myosin**) filaments and extending from one Z disk to an adjacent one; shortens during contraction. (Figures 17-29 and 17-30)

sarcoplasmic reticulum
Network of membranes in cytoplasm of a muscle cell that sequesters Ca^{2+} ions; release of stored Ca^{2+} induced by muscle stimulation triggers contraction. (Figure 17-32)

saturated
Referring to a compound (e.g., fatty acid) in which all the carbon-carbon bonds are single bonds.

scaffold proteins
Proteins that participate in intracellular signaling by binding several proteins in a signaling pathway and localizing them to a specific region of the cell.

scanning electron microscopy (SEM)
A type of electron microscopy that yields the three-dimensional structure of samples. Samples are coated with a thin film of metal, and then an intense beam of electrons scans the sample to generate secondary electrons that generate the image.

SCF
Ubiquitin-protein ligase that ubiquitinylates inhibitors of S-phase CDKs and many other proteins, marking them for degradation by proteasomes.

Schwann cells
Glial cells in the peripheral nervous system that create myelin sheaths that wrap around and insulate peripheral neuronal axons.

second messenger
A small intracellular molecule (e.g., cAMP, cGMP, Ca^{2+}, DAG, and IP_3) whose concentration increases (or decreases) in response to binding of an extracellular signal and that functions in **signal transduction**. (Figure 15-5)

secondary structure
In proteins, local folding of a polypeptide chain into regular structures including the α helix, β sheet, and β turns.

***secretion (sec)* mutants**

A collection of temperature-sensitive mutants isolated in yeast that block protein secretion at the nonpermissive temperature.

secretory pathway
Cellular pathway for synthesizing and sorting soluble and membrane proteins localized to the endoplasmic reticulum, Golgi, and lysosomes; plasma membrane proteins; and proteins eventually secreted from the cell. (Figure 14-2)

securin
A protein that prevents the onset of chromosome segregation by inhibiting separase, the protease that cleaves cohesin.

segregation
The process that distributes an equal complement of chromosomes to daughter cells during mitosis and meiosis.

selectins
A family of **cell-adhesion molecules** that mediate Ca^{2+}-dependent interactions with specific oligosaccharide moieties in glycoproteins and glycolipids on the surface of adjacent cells or in extracellular glycoproteins. (Figures 20-2 and 20-42)

sensor
Measures an intra- or extracellular property and converts into a signal.

sensory neurons
Neurons that receive external stimuli and transmit them to the brain and spinal cord.

separase
A protease that cleaves cohesin, thereby initiating chromosome segregation.

short interspersed elements (SINEs)
In mammals, repeated sequences related to a 150 (in mice)–300 (in humans) base-pair sequence that has been transposed throughout the genome over evolutionary time by proteins encoded by a long interspersed element (LINE) in the same organism. (Table 7-1)

shuttle vector
Plasmid vector capable of propagation in two different hosts. (Figure 6-15)

signal amplification
The aspect of a signal transduction pathway whereby activation by a small number of signaling molecules leads to an effect on many times that number of target molecules.

signal-anchor sequence (SA)
A hydrophobic N-terminal sequence that serves as an ER-targeting signal sequence and becomes a hydrophobic transmembrane-spanning sequence.

signal-based targeting
A process that involves the targeting of a newly synthesized protein from the cytoplasm to an intracellular organelle.

signaling cascade
Pathway that is activated by an intracellular or extracellular event and then transmits the signal to an **effector**.

signaling molecule
General term for any extracellular or intracellular molecule involved in mediating the response of a cell to its external environment or to other cells.

signal peptide
See **targeting sequence**.

signal recognition particle (SRP)
A cytosolic ribonucleoprotein particle that binds to the ER **signal sequence** in a nascent secretory protein and delivers the nascent chain/ribosome complex to the ER membrane, where synthesis of the protein and translocation into the ER are completed. (Figure 13-5)

signal sequence
See **targeting sequence**.

signal transduction pathway
The set of proteins or small molecules involved in relaying a chemical message from the receptor at the cell surface to the target molecule(s) inside the cell.

silencer sequences
DNA sequences capable of binding transcription regulation factors (repressors). (Figure 8-31)

simple diffusion
Net movement of a molecule across a membrane down its concentration gradient at a rate proportional to the gradient and the permeability of the membrane; also called *passive diffusion*.

simple-sequence (satellite) DNA

Short, tandemly repeated sequences that are found at **centromeres** and **telomeres** as well as at other chromosomal locations and are not transcribed.

single cell RNA-Seq (scRNA-Seq)
A method that allows analysis of the abundance of specific mRNAs from a single cell. Typically, mRNA extracted from a single cell is converted to cDNA with the enzyme reverse transcriptase, and particular gene sequences are amplified by PCR and then sequenced. The relative number of reads from a particular mRNA is used to estimate abundance.

single-pass membrane protein
A membrane protein that contains a single transmembrane-spanning domain.

siRNA (short interfering RNA)
A small, double-stranded RNA, 21–23 nucleotides long with two single-stranded nucleotides at each end. A single strand of the siRNA associates with several proteins to form an **RNA-induced silencing complex (RISC)** that cleaves target RNAs to which the siRNA base pairs perfectly; variously called *short* or *small interfering RNA* and *small inhibitory RNA*. siRNAs can be designed to experimentally inhibit expression of specific genes. See also **miRNA**. (Figure 9-31b)

siRNA knockdown
Technique for experimentally inhibiting translation of a specific mRNA by use of **siRNA**; useful for reducing the activity of a protein, particularly in organisms that are not amenable to classical genetic methods for isolating loss-of-function mutants.

sister chromatid resolution
The process of untangling of the intertwined **sister chromatids** during prophase.

sister chromatids
The two identical DNA molecules created during DNA replication and the associated chromosomal proteins. After DNA replication, each chromosome is composed of two sister chromatids.

SM proteins
Sec1/Munc18-like proteins, which bind syntaxin and are required for SNARE-mediated fusion of synaptic vesicles to a cell membrane.

Smads
Class of transcription factors that are activated by phosphorylation following binding of members of the **transforming growth factor beta (TGFβ)** family of signaling molecules to their cell-surface receptors. (Figure 16-24)

smooth endoplasmic reticulum
The region of the endoplasmic reticulum bereft of ribosomes; site of synthesis of many types of lipids and phospholipids.

SNAREs
Cytosolic and integral membrane proteins that promote fusion of vesicles with target membranes. Interaction of **v-SNAREs** on a vesicle with cognate **t-SNAREs** on a target membrane forms very stable complexes, bringing the vesicle and target membranes into close apposition. (Figure 14-11)

snoRNA (small nucleolar RNA)
A type of small, stable RNA that functions in rRNA processing and base modification in the nucleolus.

snRNA (small nuclear RNA)
One of several small, stable RNAs localized to the nucleus. Five snRNAs are components of the **spliceosome** and function in splicing of pre-mRNA. (Figures 9-9 and 9-10)

snRNPs (small ribonuclear particles) U1, U2, U4, U5, and U6
Five smaller ribonucleoprotein complexes that are assembled on the snRNAs with the same names. The U1, U2, U4, U5, and U6 snRNPs associate transiently with each other and with splice sites in pre-mRNAs to assemble the **spliceosome**.

somatic cell
Any plant or animal cell other than a germ cell.

sorting signal
A relatively short amino acid sequence within a protein that directs the protein to particular transport vesicles as they bud from a donor membrane in the secretory or endocytic pathway. (Table 14-2)

Southern blotting
Technique for detecting specific DNA sequences separated by electrophoresis by hybridization to a labeled nucleic acid probe.

special-pair chlorophylls
Two chlorophyll molecules in a photosynthetic reaction center that can transfer energy to an electron and thus initiate photoelectron transport. These chlorophylls obtain the energy either by directly absorbing light energy or by resonance energy transfer from antenna pigments.

specificity

The ability of immune cells or their products to distinguish between structurally closely related molecules.

sperm
The male gamete — a motile haploid cell that can bind to and fuse with an egg cell, forming a zygote.

S-phase cyclin-CDKs
Cyclin-CDK complexes that promote the initiation of DNA replication.

sphingolipid
Major group of membrane lipids, derived from sphingosine, that contain two long hydrocarbon chains and either a phosphorylated head group (sphingomyelin) or carbohydrate head group (cerebrosides, gangliosides). (Figure 10-8b)

spindle pole bodies
Functionally analogous structure of centrosomes in yeast.

splicing enhancers
The RNA sequences bound by RNA-binding proteins that stimulate RNA splicing.

splicing silencers
The RNA sequences bound by RNA-binding proteins that inhibit RNA splicing.

spliceosome
Large ribonucleoprotein complex that assembles on a pre-mRNA and carries out **RNA splicing**.

SR proteins
A subset of hnRNP proteins that bind exonic splicing enhancers.

SRE-binding proteins (SREBPs)
Cholesterol-dependent transcription factors, localized in the ER membrane, that are activated in response to low cellular cholesterol levels and then stimulate expression of genes encoding proteins involved in cholesterol synthesis and import as well as synthesis of other lipids.

SRP receptor
The receptor for the **signal recognition particle (SRP)**, located in the membrane.

starch

A very long, branched polysaccharide, composed exclusively of glucose units, that is the primary storage carbohydrate in plant cells. (Figure 12-32)

steady state
In cellular metabolic pathways, the condition when the rate of formation and rate of consumption of a substance are equal, so that its concentration remains constant. (Figure 2-23)

stem cell
A self-renewing cell that can divide *symmetrically* to give rise to two daughter cells whose developmental potential is identical to that of the parental stem cell or *asymmetrically* to generate daughter cells with different developmental potentials. (Figures 22-11 and 22-12)

stem-cell niche
A set of cells, extracellular matrices, and hormones that surrounds a stem cell and that maintains its stem-cell properties.

step size
Used when describing the movement of a molecular motor such as myosin, kinesin, or dynein; the distance the motor moves during one cycle of ATP hydrolysis.

stereoisomers
Two compounds with identical molecular formulas whose atoms are linked in the same order but in different spatial arrangements. In *optical isomers*, designated D and L, the atoms bonded to an asymmetric carbon atom are arranged in a mirror-image fashion. *Geometric isomers* include the *cis* and *trans* forms of molecules containing a double bond.

stop-transfer anchor sequence (STA)
A sequence that functions both to stop passage of the polypeptide chain through the translocon and to become a hydrophobic transmembrane segment in the membrane bilayer.

strand invasion
An early step in DNA recombination catalyzed by RecA in bacteria and Rad51 in eukaryotes in which a single-stranded region of DNA with a free 3′ end hybridizes to its complementary strand in a second double-stranded DNA molecule. The complementary strand of this target double-stranded DNA is displaced as a single-stranded loop of DNA over the region of hybridization to the invading strand. (Figures 5-20 and 5-21)

stress fibers

Contractile F-actin- and myosin II-containing structures associated with focal adhesions whose formation is under control of the small GTPase Rho.

stroma
The fluid-filled compartment in a chloroplast between the thylakoid membrane and the inner membrane in which carbon fixation and starch synthesis in stage 4 of photosynthesis take place.

structural motif
A particular combination of two or more secondary structures that form a distinct three-dimensional structure that appears in multiple proteins and that often, but not always, is associated with a specific function.

substrate
Molecule that undergoes a charge in a reaction catalyzed by an enzyme.

substrate-level phosphorylation
Formation of ATP from ADP and P_i catalyzed by cytosolic enzymes in reactions that do not depend on a proton-motive force or molecular oxygen.

suprachiasmatic nucleus (SCN)
A collection of neurons in the region of the brain called the *hypothalamus*. It functions as a master clock or central pacemaker for circadian rhythms in mammals.

supercomplexes
Very large assemblies of protein complexes that participate in pathways. The assembly of the supercomplexes improves the speed and efficiency of these pathways.

superoxide anions
One type of reactive oxygen species in which an unpaired electron is added to molecular oxygen (O_2) to form the anion $O_2^{\bullet -}$.

SWI/SNF chromatin-remodeling complex
A multiprotein chromatin-remodeling co-activator complex with at least one subunit that is homologous to DNA helicases that facilitates nucleosomes sliding along DNA and decondensation of condensed chromatin structures.

symmetric cell division
Separation of a cell into two daughter cells that look and function exactly like the parent cell. In higher eukaryotes, it involves division of the nucleus (mitosis) and of the cytoplasm (cytokinesis); mitosis often is used to refer to both nuclear and cytoplasmic division. (Figure 22-1a).

symport
A type of **cotransport** in which a membrane protein (*symporter*) transports two different molecules or ions across a cell membrane in the *same* direction. See also **antiport**. (Figure 11-3, **[3B]**)

symporter
An integral membrane protein that functions as a cotransporter to transport two molecules in the same direction across a membrane.

synapse
Specialized region between an axon terminal of a neuron and an adjacent neuron or other excitable cell (e.g., muscle cell) across which impulses are transmitted. At a *chemical* synapse, the impulse is conducted by a **neurotransmitter**; at an *electric* synapse, impulse transmission occurs via **gap junctions** connecting the pre- and postsynaptic cells. (Figure 23-3)

synapse elimination
A process during nervous system development during which synaptic connections are removed.

synaptic plasticity
The modification of synaptic connectivity based on neuronal experience, which is a biological manifestation of forming and storing memories.

synaptic vesicles
Small vesicles in axon termini that contain a neurotransmitter and that undergo exocytosis following arrival of an action potential.

synaptonemal complex (SC)
Proteinaceous structure that mediates the association (synapsis) between homologous chromosomes during prophase of meiosis I.

syntelic attachment
Indicates that kinetochores of a **sister chromatid** pair attach to microtubules emanating from the same pole.

synteny
Occurrence of genes in the same order on a chromosome in two or more different species.

talin

An intracellular, mechanosensory protein that functions as a regulated adapter which binds to the cytoplasmic tail of the ß subunit of integrins.

target cell
A cell that senses and responds to a signal, often a protein or small molecule, sent by another cell.

targeting sequence
A relatively short amino acid sequence within a protein that directs the protein to a specific location within the cell; also called *signal peptide, signal sequence,* and *uptake-targeting sequence*. (Table 13-1)

tastants
Water-soluble molecules that activate taste receptors.

taste receptors
A class of receptors that bind to tastants to activate the sense of taste.

Tat
An HIV-encoded protein that prevents Pol II termination when synthesizing the polycistronic HIV mRNA, thereby allowing transcription of the complete proviral DNA genome.

TATA box
A conserved sequence in the **promoter** of many eukaryotic protein-coding genes where the transcription-initiation complex assembles. (Figure 8-11)

TATA box–binding protein (TBP)
A subunit of TFIID (a general transcription factor), TBP is the first protein to bind to a TATA box promoter. All eukaryotic TBPs analyzed to date have very similar C-terminal domains of 180 residues. This domain of TBP folds into a saddle-shaped structure; the two halves of the molecule exhibit an overall dyad symmetry but are not identical. TBP interacts with the minor groove in DNA, bending the helix.

T cell
A lymphocyte that matures in the thymus and expresses antigen-specific receptors that bind antigenic peptides complexed to MHC molecules. There are two major classes: *cytotoxic* T cells (CD8 surface marker, class I MHC restricted, kill virus-infected and tumor cells) and *helper* T cells (CD4 marker, class II MHC restricted, produce cytokines, required for activation of B cells). (Figures 24-36 and 24-40)

T-cell receptor (TCR)
A heterodimeric antigen-binding transmembrane protein containing variable and constant regions and associated with the signal-transducing multimeric CD3 complex. (Figure 24-30)

telomerase
The enzyme which adds repeated telomere sequences that are needed to protect the ends of linear chromosomes.

telomere
Region at each end of a eukaryotic chromosome containing multiple tandem repeats of a short telomeric (TEL) sequence. Telomeres are required for proper chromosome **segregation** and are replicated by a special process that prevents shortening of chromosomes during DNA replication. (Figure 7-40)

telophase
Final mitotic stage, during which the nuclear envelope re-forms around the two sets of separated chromosomes, the chromosomes decondense, and division of the cytoplasm (cytokinesis) is completed. (Figures 18-38 and 18-39)

temperature-sensitive (ts) mutation
A mutation that produces a wild-type phenotype at one temperature (the permissive temperature) but a mutant phenotype at another temperature (the nonpermissive temperature). This type of mutation is especially useful in identification of genes essential for life. (Figure 6-6)

termination
The end of the process of **transcription**.

termination, transcription
Cessation of the synthesis of an RNA chain. (Figure 5-24)

tertiary structure
In proteins, overall three-dimensional form of a polypeptide chain, which is stabilized by multiple noncovalent interactions between side chains. (Figure 3-10a)

thick filaments
Myosin-II-containing filaments of muscle in which the myosin molecules assemble into bipolar structures.

thin filaments
Actin-containing filaments of muscle.

3′ cleavage/polyadenylation
Transcription by RNA polymerase II terminates at any one of multiple termination sites downstream from the poly(A) site, which is located at the 3′ end of the final exon. After the primary transcript is cleaved at the poly(A) site a string of adenosine (A) residues is added. (Figure 9-2)

thylakoid lumen
A single continuous compartment constituted by the spaces within all the thylakoids.

thylakoid membrane
A membrane separating the stroma and the thylakoid spaces. Protons in the thylakoid lumen are pumped across the thylakoid membrane to generate a proton-motive force.

thylakoids
Flattened membranous sacs in a chloroplast that can be arranged in stacks and contain the photosynthetic pigments and **photosystems**. (Figure 12-33)

thrombopoietin
A cytokine that stimulates the development of megakaryocytes, cells that form the platelets involved in blood clotting.

thymosin-β_4
A protein that binds reversibly to ATP-actin in such a way that it cannot polymerize; this interaction provides a reservoir of actin for polymerization when it dissociates from thymosin-β_4.

tight junction
A type of cell-cell junction between the plasma membranes of adjacent epithelial cells that prevents diffusion of macromolecules and many small molecules and ions in the spaces between cells and diffusion of membrane components between the apical and basolateral regions of the plasma membrane. (Figure 20-17)

tolerance
The absence of an immune response to a particular antigen or set of antigens.

Toll-like receptor (TLR)
Member of a class of cell-surface and intracellular receptors that recognize a variety of microbial products. Ligand binding initiates a signaling pathway that induces various responses depending on the cell type. (Figure 24-37)

topogenic sequences

Segments within a protein whose sequence, number, and arrangement direct the insertion and orientation of various classes of transmembrane proteins into the endoplasmic reticulum membrane. (Figure 13-14)

topology
The basic structural arrangement of a membrane protein according to the orientation of transmembrane segment within the membrane. The membrane topology usually remains fixed after it is established during synthesis in the ER.

totipotent
Describes a stem cell that is able to give rise to all of the types of differentiated cells in an organism. Also describes the zygote, as it is able to generate every cell type in the body as well as placental cells.

trans (intercellular) interactions
Binding interactions between molecules on the plasma membranes of different cells.

transcellular pathway
The pathway by which molecules and ions move from one side of an epithelium to the other by crossing the apical and basolateral membranes via transporters, pumps, or channels.

transcellular transport
A two-stage process whereby molecules are imported through the plasma membrane on the **apical** side of the cells and exported through the plasma membrane on the **basolateral** (blood-facing) side (see Figures 11-25d and 11-30).

transcription
Process in which one strand of a DNA molecule is used as a template for synthesis of a **complementary** RNA by RNA polymerase. (Figures 5-23 and 5-24)

transcription-control region
A specific DNA sequence that serves as the binding site for **transcription factors** that regulate **transcription**.

transcription factor
General term for any protein, other than RNA polymerase, required to initiate or regulate transcription in eukaryotic cells. *General* factors, required for transcription of all genes, participate in formation of the transcription-preinitiation complex near the start site. *Specific* factors stimulate (**activators**) or inhibit (**repressors**) transcription of particular genes by binding to their regulatory sequences.

transcription unit
A region in DNA, bounded by an initiation (start) site and termination site, that is transcribed into a single primary transcript.

transcytosis
Mechanism for transporting certain substances across an epithelial sheet that combines **receptor-mediated endocytosis** and **exocytosis**. (Figures 14-25 and 24-11)

transfection
Experimental introduction of foreign DNA into cells in culture, usually followed by expression of genes in the introduced DNA. (Figure 6-34)

transfer RNA (tRNA)
A group of small RNA molecules that function as amino acid donors during protein synthesis. Each tRNA becomes covalently linked to a particular amino acid, forming an aminoacyl-tRNA. (Figures 5-31 and 5-32)

transformation
(1) Permanent, heritable alteration in a cell resulting from the uptake and incorporation of a foreign DNA into the host-cell genome; also called *stable transfection*. (2) Conversion of a "normal" mammalian cell into a cell with cancer-like properties usually induced by treatment with a virus or other cancer-causing agent.

transforming growth factor beta (TGFβ)
A family of secreted signaling proteins that are used in the development of most tissues in most or all animals. Members of the TGFβ family more often inhibit growth than stimulate it. Mutations in TGFβ signal transduction components are implicated in human cancer, including breast cancer. (Figure 16-24)

***trans*-Golgi network (TGN)**
Complex network of membranes and vesicles that serves as a major branch point in the **secretory pathway**. Vesicles budding from this most distal Golgi compartment carry membrane and soluble proteins to the cell surface or to lysosomes. (Figures 14-2 and 14-18)

transition state
State of the reactants during a chemical reaction when the system is at its highest energy level; also called the **transition-state intermediate**.

transition-state intermediate
See **transition state**.

translation

The **ribosome**-mediated assembly of a polypeptide whose amino acid sequence is specified by the nucleotide sequence in an mRNA. (Figure 5-29)

translocon
Multiprotein complex in the membrane of the rough endoplasmic reticulum through which a nascent secretory protein enters the ER lumen as it is being synthesized. (Figure 13-7)

transmission electron microscope (TEM)
A type of electron microscopy whereby electrons pass through the specimen to form an image.

transport protein
See **membrane transport protein**.

transport vesicle
A small, membrane-bounded compartment that carries soluble and membrane "cargo" proteins in the forward or reverse direction in the **secretory pathway**. Vesicles form by budding off from the donor organelle and release their contents by fusion with the target membrane.

transporters
Membrane proteins that undergo conformational changes as they move a wide variety of ions and molecules across cell membranes at a slower rate than channels. See *uniporter*, *symporter*, and *antiporter* in Figure 11-3.

transposable (mobile) DNA element
Any DNA sequence that is not present in the same chromosomal location in all individuals of a species and can move to a new position by **transposition**; also called *mobile DNA element* and *interspersed repeat*. (Table 7-1)

transposition
Movement of a **transposable DNA element** within the genome; occurs by a cut-and-paste mechanism or copy-and-paste mechanism depending on the type of element. (Figure 7-8)

treadmilling
The two ends of a myosin-decorated actin filament grow at different rates. Because the critical concentrations for the two ends are different, at steady state the free ATP–G-actin will be intermediate between C_{c^+} and C_{c^-}, so the (+) end will grow and the (−) end will lose subunits. This phenomenon is known as *treadmilling* because particular subunits appear to move through the filament. (Figure 17-10b)

triacylglycerol (triacylglyceride)
Major form in which fatty acids are stored and transported in animals; consists of three fatty acyl chains esterified to a glycerol molecule.

trophectoderm (TE)
The part of an early mammalian embryo that will form the extra-embryonic tissues, including the placenta but not the embryo proper.

trophic factor
Any of numerous signaling proteins required for the survival of cells in multicellular organisms; in the absence of such signals, cells often undergo "suicide" by **apoptosis**.

tropomodulin
A protein that binds the (−) end of an actin filament to inhibit assembly and disassembly.

tropomyosin
A long rope-like coiled-coil protein that binds along the sides of actin filaments to stabilize them, and also binds the troponin complex involved in Ca^{2+}-mediated skeletal muscle contraction.

t-SNAREs
See **SNAREs**.

tubulin
A family of globular cytoskeletal proteins that polymerize to form the cylindrical wall of **microtubules**. (Figure 18-3)

tumor microenvironment
The complex multicellular structure of a tumor, including multiple subtypes of cancer cells and normal cells that have been recruited to the tumor. T cells from the immune system are an important component of the tumor microenvironment.

tumor suppressor gene
Any gene whose encoded protein directly or indirectly inhibits progression through the cell cycle and in which a loss-of-function mutation is oncogenic. Inheritance of a single mutant allele of many tumor suppressor genes (e.g., *RB, APC,* and *BRCA1*) greatly increases the risk for developing colorectal and other types of cancer. (Figure 25-21)

tumorigenesis
The incremental process by which a tumor develops, starting from an altered somatic cell that acquires the ability to grow in an uncontrolled fashion.

ubiquinone [coenzyme Q (CoQ)]
A hydrophobic small, organic molecule that carries two protons and two electrons in electron-transport pathways, cycling between the oxidized (ubiquinone) and reduced (dihydroquinone) forms.

ubiquitin
A small protein that can be covalently linked to other intracellular proteins, thereby tagging these proteins for degradation by the **proteasome**, sorting to the lysosome, or alteration in the function of the target protein. (Figure 3-32)

ubiquitinylation
The enzymatic, covalent attachment of the small protein ubiquitin to a protein.

uncoupler
Any natural substance (e.g., the protein thermogenin) or chemical agent (e.g., 2,4-dinitrophenol) that dissipates the **proton-motive force** across the inner mitochondrial membrane or thylakoid membrane of chloroplasts, thereby inhibiting ATP synthesis.

uncoupling protein 1 (UCP1)
A transporter protein in the inner mitochondrial membrane, especially in brown-fat adipocytes, that uncouples oxidative phosphorylation and ATP generation by dissipating the proton-motive force via transporting of protons from the innermembrane space into the matrix.

unfolded-protein response
The stress-response pathway that responds to accumulation of unfolded proteins in the ER by activating expression of enzymes for protein folding in the ER.

uniport
A transmembrane protein that transports a single type of molecule down its concentration gradient.

unsaturated
Referring to a compound (e.g., fatty acid) in which one of the carbon-carbon bonds is a double or triple bond.

upstream
(1) For a gene, the direction opposite to that in which RNA polymerase moves during transcription. Nucleotides upstream from the +1 position (the first transcribed nucleotide) are designated −1, −2, and so on. (2) Events that occur earlier in a cascade of steps (e.g., signaling pathway). See also **downstream**.

upstream activating sequence (UAS)
Any protein-binding regulatory sequence in the DNA of yeast and other simple eukaryotes that is necessary for maximal gene expression; equivalent to an enhancer or promoter-proximal element in higher eukaryotes. (Figure 8-18)

vaccine
An innocuous preparation derived from a pathogen and designed to elicit an immune response in order to provide immunity against a future challenge by a virulent form of the same pathogen.

vacuole
A membrane-limited plant organelle that stores water, ions, and small-molecule nutrients and may have a degradative function similar to that of lysosomes in animal cells.

van der Waals interaction
A weak **noncovalent interaction** due to small, transient asymmetric electron distributions around atoms (dipoles). (Figure 2-10)

vector
In cell biology, an autonomously replicating genetic element used to carry a cDNA or fragment of genomic DNA into a host cell for the purpose of gene cloning. Commonly used vectors are bacterial plasmids and modified bacteriophage genomes. See also **shuttle vector**. (Figure 6-13)

viral envelope
A phospholipid bilayer forming the outer covering of some viruses (e.g., influenza and rabies viruses); derived by budding from a host-cell membrane and contains virus-encoded glycoproteins. (Figure 5-41)

virion
An individual viral particle.

virus
A small, intracellular parasite, consisting of nucleic acid (RNA or DNA) enclosed in a protein coat, that can replicate only in a susceptible host cell; widely used in cell biology research. (Figure 5-40)

V_{max}
Parameter that describes the maximal velocity of an enzyme-catalyzed reaction or other process such as protein-mediated transport of molecules across a membrane. (Figures 3-25 and 11-5)

v-SNAREs
A family of small proteins that reside in the membrane of transport vesicles, and through their specific association with similar proteins in the target membrane bring about vesicle membrane fusion. See also **SNAREs**.

voltage-gated channels
Membrane channels that open or close in response to changes in the electrical potential across the cell membrane.

Warburg effect
Describes the observation that most cancer cells predominantly produce energy by glycolysis followed by fermentation of pyruvate to lactic acid. While normal cells use this form of energy production only under the oxygen-limiting (anaerobic) condition, cancer cells metabolize glucose in this manner even in the presence of sufficient oxygen. The process is thus also referred to as *aerobic glycolysis*.

WASp
A nucleation promoting factor involved in the activation of the Arp2/3 complex.

Wee1
protein-tyrosine kinase; phosphorylates CDKs on threonine 14 and tyrosine 15 to inhibit CDK activity.

whole transcriptome shotgun sequencing (RNA-Seq)
A method that allows sequencing of the transcribed portion of the genome. mRNAs extracted from a tissue sample are converted to cDNA with the enzyme reverse transcriptase. The mRNAs present in the sample and their relative abundance can be determined by sequencing of a large number of cDNAs.

wild type
Normal, nonmutant form of a gene, protein, cell, or organism.

Wnt
A family of secreted signaling proteins used in the development of most tissues in most or all animals. Mutations in Wnt signal transduction components are implicated in human cancer, especially colon cancer. Receptors are Frizzled-class proteins with seven transmembrane segments. (Figure 16-26)

xeroderma pigmentosum
A rare inherited disease due to inactivating mutations in any of seven genes encoding proteins involved in DNA nucleotide excision repair. Patients are abnormally sensitive to

the UV in sunlight and have a high incidence of multiple types of skin cancer.

x-ray crystallography
Commonly used technique for determining the three-dimensional structure of macromolecules (particularly proteins and nucleic acids) by passing x-rays through a crystal of the purified molecules and analyzing the diffraction pattern of discrete spots that results. (Figure 3-48)

zinc finger
Several related DNA-binding **structural motifs** composed of secondary structures folded around a zinc ion; present in numerous eukaryotic transcription factors. (Figures 3-7c and 8-25a, b)

With its acclaimed author team, cutting-edge content, emphasis on medical relevance, and coverage based on key experiments, *Molecular Cell Biology* has justly earned an impeccable reputation as an exciting and authoritative textbook. Avoiding an encyclopaedic approach, the book grounds its coverage in the experiments that define our understanding of cell biology, engaging students with the exciting breakthroughs that define the field's history and point to its future. The authors, all world-class researchers and teachers, incorporate medically relevant examples where appropriate to help illustrate the connections between cell biology and health and human disease.

Achieve

The ninth edition is now available in Achieve. Achieve supports educators and students throughout the full range of instruction, including assets suitable for pre-class preparation, in-class active learning, and post-class study and assessment. The pairing of a powerful new platform with outstanding biology content provides an unrivalled learning experience.

Features of Achieve include:

- A design guided by learning science research. Co-designed through extensive collaboration and testing by both students and faculty.
- A learning path of powerful content including pre-class, in-class, and post-class activities and assessments.
- Easy integration and gradebook sync with iClicker classroom engagement solutions.
- Powerful content such as the new Smart Biology Animated Videos, which provide cutting-edge 3-D tools for students to help them understand cell biology at a structural level.
